Professor Christine V. Rich

Professor Steven Van Lanen

DEDICATION

This dissertation is dedicated to my parents

Late Mr. Anantha reddy Veerareddygar

and

Mrs. Vijaya Lakshmi Veerareddygar

Without your emotional support and intellectual guidance, I would not have made
it this far. Thank you.

ACKNOWLEDGEMENTS

I owe my deepest gratitude to my mentor, Dr. Eugene G. Mueller. His insightful guidance allowed me to think critically and to develop a constructive thought process. I had the great opportunity of taking his course in Biochemistry during my first year at the graduate school which spiked my interest to pursue research in the field of enzymology. His vast knowledge allowed me to learn valuable research skills that I hope to apply through my career. Without his helpful guidance, I would never have completed this dissertation. Thank you.

I thank my committee members, Dr. Muriel C. Maurer, Dr. Christine V. Rich, and Dr. Steven Van Lanen for their insightful advice, guidance, support and helpful suggestions. I owe many thanks especially to Dr. Muriel C. Maurer for the knowledge and intellectual experience that I have gained as her teaching assistant during the first four years of my graduate life. I owe Dr. Christine V. Rich for refreshing my knowledge in organic chemistry and spectroscopy through her advanced spectroscopy lectures. I thank Dr. Steven Van Lanen for generously providing the plasmids required for the overexpression of enzymes.

I thank my previous lab mates, Dr. Sanjay K. Singh who was always willing to help when I needed it the most, Dr. Edward J. Miracco who taught me how to handle enzymes, and had been offering continuous help even after graduating, Dr. Menakshi Bansal for her expertise with RNA techniques, Yizhou Xie for his help with benchwork. I would like to thank my current lab member James Ladd for sharing his knowledge in synthetic chemistry.

I thank Dr. Neal J. Stolowich for his help with running NMR, Dr. Bogdan Bogdanov and Dr. Pawel Lorkiewicz for helping me with the acquisition of FT-MS data.

I owe a debt of gratitude to the Milliner family (Sarah and Scott Milliner), and their two beautiful daughters (Norah and Isabel), and the Raeuchle family (Clara and Keith Raeuchle) for their extended hospitality that made my life in Louisville a pleasant one.

I thank my former and present colleagues at the department of Chemistry including Katherine Sellers, Mohamed Marei, Sébastien Laulhé, and Rajat Chauhan for all the fun times and valuable discussions that we had.

I thank the taxpayers who funded my research through NIH, and the University of Louisville “Bucks for Brains” program.

ABSTRACT

MECHANISTIC INVESTIGATIONS OF PSEUDOURIDINE SYNTHASES—A SURPRISING GLYCAL INTERMEDIATE LIES ON THE REACTION PATHWAY

Govardhan reddy Veerareddygar

December 10, 2014

Pseudouridine synthases (ΨSs) catalyze the isomerization of uridine (U) in RNA to pseudouridine (Ψ), which is the most common post-transcriptional modification in RNAs and is ubiquitous within all three domains of life. ΨSs are classified into six different families based on sequence alignments and have a universally conserved aspartic acid residue ('conserved Asp' for simplicity) that is absolutely essential for activity. RNA containing 5-fluorouridine ([F⁵U]RNA) has been used as a mechanistic probe. Upon incubation with [F⁵U]RNA, TruA and RluA get irreversibly inhibited and appear in a protein-RNA adduct band on denaturing PAGE gels, which is consistent with the 'Michael mechanism' that proposes a covalent adduct between the conserved Asp and the pyrimidine ring. *E. coli* TruB does not get inhibited upon incubation with [F⁵U]RNA, nor does it form an adduct and instead converts F⁵U into two rearranged, hydrated products. ¹⁸O labeling studies with the *E. coli* ΨSs TruA, TruB, RluA, and TruD show that the

hydration of the products of F⁵U occurs directly from solution and not through the hydrolysis of a Michael adduct. These ¹⁸O labeling studies were extended here to *Thermotoga maritima* TruB (TmTruB) which showed a behavior intermediate between that of *E. coli* TruB (no observed adduct; multiple turnovers) and RluA and TruA (stoichiometric adduction; single turnover). ¹⁸O label is incorporated into RNA directly from solvent during the reaction of [F⁵U]RNA catalyzed by TmTruB. These results are consistent with the scheme proposed earlier for the handling of F⁵U by ΨSs. Among examined ΨSs, TmTruB uniquely shows the interesting ability to catalyze the dehydration and rehydration of the products of F⁵U.

The minor product of F⁵U from the action of ΨSs is an *arabino* isomer and its generation requires epimerization at C2', which suggested that the ΨS mechanism may proceed by deprotonation of C2' to eliminate the uracil and form a glycol intermediate. To test this mechanistic possibility, substrate RNA stem-loops containing [2'-²H]uridine were prepared and used to measure the deuterium kinetic isotope effect on the conversion of U to Ψ. Deuteration at C2' reduced both $V_{\max}$ and $V_{\max}/K_m$ for the reaction as catalyzed by TruB (2.54-fold and 3.58-fold, respectively) and RluA (1.79-fold and 2.17-fold, respectively). These results conclusively indicate that the deprotonation of C2' occurs in a partially rate-determining step in the conversion of U to Ψ, which is consistent with the 'glycol mechanism' but inconsistent with the proposed alternatives.

CHAPTER 1

PSEUDOURIDINE AND THE PSEUDOURIDINE SYNTHASES

Pseudouridine (Ψ), the C-glycoside isomer of uridine (U) is a ubiquitous constituent of structural RNAs, and it is the most common post-transcriptional modification in all three domains of life (Figure 1.1). The enzymes that catalyze this isomerization of U to Ψ are the pseudouridine synthases (Ψ synthases), and they use both sequence and structural information to achieve site-specific generation of Ψ in particular RNA contexts. [1]

Pseudouridine and its physiological significance

The existence of Ψ in yeast tRNA was reported in 1957, [2] and Ψ was subsequently found in all non-coding RNAs. [2] In 1970, Johnson and Söll reported site-specific Ψ synthase activity in *Escherichia coli* extracts. [3] Most recently, Carlile and co-workers reported Ψ in mRNAs and showed that its occurrence is heavily regulated. [4] Pseudouridine is physically and chemically distinct from its parent uridine. The C-C glycosidic bond in Ψ exhibits enhanced rotational freedom as compared to the C-N glycosidic bond in U. [5] CD spectroscopy [6], nuclear magnetic resonance (NMR) studies, [6] and molecular dynamic simulations [7] all suggest that Ψ imparts structural rigidity in both single- and double-stranded RNAs, possibly due to the free imino proton in Ψ that can act as an additional hydrogen bond donor. [8] The presence of Ψ in an *anti* configuration

Figure 1.1: The isomerization of U to Ψ

in polynucleotide chains provides an appropriate geometry for coordination of a water molecule between the imino proton and the 5'-phosphate backbone of its preceding residue, thereby restricting the base conformation and mobility of the backbone. [8] Additionally, Ψ enhances local RNA stacking, which is perhaps the most important contribution of Ψ towards stabilizing the RNA structure. [8]

The ubiquity of Ψ across all forms of RNA emphasizes its physiological importance. Lack of Ψ at positions 1911, 1915, and 1917 of 23S rRNA in *E. coli* causes severe growth retardation. [9-11] In *Thermus thermophilus*, Ψ 55 in tRNA is essential for the low temperature adaptation of this extremophile. [12] Depletion of the Ψ synthase encoded by *minifly* in *Drosophila* results in a severe reduction in the wing size by decreasing both the number and size of wing cells (due to cell death rather than reduced cell proliferation). [13] Mutations in the human gene *dyskerin*, an ortholog of the Ψ synthase-encoding *Cbf5* gene is shown to be associated with the X-linked form of dyskeratosis congenita, a rare hematopoietic and malignant disorder. [14-16] Individuals with this disorder show increased cancer susceptibility, failure in ribosome biogenesis, and cells with decreased telomerase activity that results in a difficulty maintaining the telomere length. [14-16] In humans, a single mutation in the *PUS1* gene has been correlated with mitochondrial myopathy and sideroblastic anemia. [17] The tRNAs of patients with this affliction lack the Ψ expected to be generated by Pus1p. [17]

Pseudouridine synthases

Based on sequence comparisons and structural analysis, six different families of Ψ have been classified: TruA, TruB, RluA, RsuA, TruD and PUS10,

which are named after the first cloned member of the family. [18, 19] Despite the lack of statistically significant global sequence similarity, a superimposition of the crystal structures of Ψ synthases reveals a conserved core β -domain, strongly suggestive of divergent evolution. [20] Biochemical characterization revealed that Ψ synthases do not require any cofactors for catalysis, nor do they release detectable amounts of uracil during the isomerization of U to Ψ . [21-23] The Ψ synthases share several amino acids conserved across all the families in both sequence and structure. The active site cleft of all six families shows an absolutely conserved aspartic acid residue (hereafter, the 'conserved Asp'), a conserved basic residue (Arg or Lys), and two aromatic residues (Phe or Tyr). Site-directed mutagenesis in a multitude of Ψ synthases revealed the conserved Asp to be essential for enzyme activity. [9, 10, 24-27] In cocrystal structures of several Ψ synthases with RNA, the conserved Asp lies in close proximity to the isomerized nucleotide, which supports direct participation in catalysis. [20]

Ψ synthases recognize their substrate uridine in the context of an RNA, isomerizing certain positions in particular RNA (Figure 1.2) Except for Cbf5p and its orthologs, which function as a part of an elaborate ribonucleoprotein complex, all other Ψ synthases characterized to date recognize their substrates without relying on accessory factors. [20]

Most of the mechanistic work reported in this dissertation is with the TruB family. TruB is responsible for the pseudouridylation of U55 in the I-arm stem loop (TSL) of all non-initiator tRNAs. [28] While some Ψ synthases can only handle full length tRNA as a substrate, *E. coli* TruB and RluA handle small stem-loop

substrates as well as the full-length tRNA. [29, 30] Santi and co-workers reported that the k_{cat} and K_{m} values for TruB and a 17-mer RNA oligonucleotide corresponding to the TSL of *Saccharomyces cerevisiae* tRNA^{Phe} were identical within error of the values with full-length tRNA. [29] Similar results were obtained by a predecessor in the Mueller group for RluA in a comparison of full-length *E. coli* tRNA^{Phe} and the 17-mer corresponding to its anticodon stem-loop (ASL). [30]

Proposed mechanisms for Ψ synthases

5-fluorouridine

Previous mechanistic work with Ψ synthases relied on site-directed mutagenesis and RNA containing 5-fluorouridine ([F⁵U]RNA) in the place of U (Figure 1.3). 5-Fluorouracil is a potent anti-cancer drug especially useful in treating colorectal cancer. [31] Early work by Frendewey *et al.* demonstrated the potent inhibitory action of tRNAs containing F⁵U on unfractionated tRNA Ψ synthases. [32] In their work on thymidylate synthase, Santi and co-workers demonstrated that F⁵U gets converted into several intracellular active metabolites such as 5-fluorodeoxyuridine monophosphate (F⁵dUMP), which acts as an inhibitor of thymidylate synthase, the sole *de novo* source of thymidylate for DNA replication and repair. [31, 33, 34] They further showed that thymidylate synthase irreversibly forms a Michael adduct between the thiol group of an active site cysteine residue and C6 of F⁵dUMP, thereby blocking the catalytic site. [34]

Figure 1.2: The classic ‘cloverleaf’ representation of *E. coli* tRNA^{Phe}. The T-arm stem loop is the truncated substrate for TruB, which isomerizes U55.

Inspired by this precedent, Penhoet and co-workers proposed a mechanism for Ψ synthases in their report of the characterization of TruA. [35] They proposed a nucleophilic attack by an unidentified enzymic cysteine residue at C6 of U to form a dihydropyrimidine-enzyme adduct. Such an adduct was purported to 1) enhance the lability of *N*-glycosidic bond, 2) provide an axis for the 180° rotation of the pyrimidine ring to reposition C5 for *C*-glycosidic bond formation, and 3) activate the proton on C5 of rearranged pyrimidine ring for subsequent β -elimination to give the product. [35] This proposed mechanism seemed to be supported by the observed inhibition of TruA upon incubation with sulfhydryl reagents.[35] To test this mechanistic premise, Santi and co-workers probed for the formation of covalent adduct for TruA by incubating it with full length [F⁵U]tRNA transcripts. [29] SDS-PAGE and urea-PAGE analysis of the reaction mixture showed a slower moving protein-RNA adduct band on both gels. This putative covalent adduct band disappeared when the sample was heated, and mass spectrometric analysis of the RNA from heat-denatured adduct revealed that F⁵U in the RNA was hydrated [36] However, when one or all of the three cysteines in TruA were mutated, only a very modest decrease in the activity of TruA was observed. [37] Sequence alignments subsequently revealed that no cysteine residues were conserved and instead identified the conserved Asp, which became the candidate nucleophile. [29] These observations led Santi and co-workers to the reasonable conclusion that TruA proceeds through a mechanism (the 'Michael mechanism', Figure 1.4) analogous to that of thymidylate synthase and other methyl transferases with the exception that the conserved Asp acts as the nucleophile. [36]

However, because of the lack of biochemical precedence for Asp acting as a Michael nucleophile, Santi and co-workers also proposed an alternative mechanistic scenario ('acylal mechanism', Figure 1.6) in which the conserved Asp nucleophilic attacks at C1' of U to form an acylal intermediate [36, 38] This scenario is well-precedented in retaining glycosidases. [39] The detached pyrimidine ring then rotates to reposition itself for the formation of bond between C5 and C1', and subsequent deprotonation of the C5 generates Ψ . However, because radiolabeling studies indicated that the pyrimidine ring of F^5U was attached to the enzyme, Santi and co-workers favored the Michael mechanism over the acylal mechanism. [36]

Cocrystal structure of TruB with $[F^5U]TSL$

Based on the presumption that TruB also follows the Michael mechanism and would be inhibited by $[F^5U]RNA$, Hoang and Ferré-D'Amaré cocrystallized TruB with $[F^5U]TSL$, and they fully expected to see a covalent linkage between the enzyme and the RNA. However, a noncovalent complex was observed in which the hydrated F^5U was rearranged to the C-glycoside isomer (Figure 1.5). [40] These observations led Hoang and Ferré-D'Amaré to conclude that TruB follows the Michael mechanism, but the reaction proceeds to the C-glycoside isomer. The failure to observe a covalent adduct in the cocrystal was ascribed to the slow ester hydrolysis of the rearranged Michael adduct that occurred over the course of crystal growth and diffraction analysis. [40]

Subsequent biochemical investigations by Spedalieri and Mueller, however, proved definitively that TruB neither gets inhibited by nor forms a stable adduct with $[F^5U]TSL$. [25] Instead, TruB converts the F^5U into its rearranged,

Figure 1.4: The proposed 'Michael mechanism' for Ψ synthases. The conserved Asp makes a nucleophilic attack on C6 of the pyrimidine ring to form a Michael adduct. *N*-glycosidic bond cleavage then occurs, and the pyrimidine ring makes a net 180° rotation to reposition itself for the subsequent C-glycosidic bond formation. Cleavage of the rearranged adduct followed by deprotonation at C5 completes the isomerization.

Figure 1.5: A, The hydrated product proposed by Santi and co-workers, *cis*-(5*S*,6*R*)-6-hydroxy, 5, 6-dihydro-5-fluorouridine. [29] B, The hydrated rearranged product of F⁵U (*cis*-(5*S*,6*R*)-5-fluoro, 6-hydroxypseudouridine) observed by Hoang and Ferré D'Amaré in the cocrystal structure of TruB with [F⁵U]TSL. [40]

Figure 1.6: The 'acylal mechanism' for Ψ formation, which begins with the conserved Asp making a nucleophilic attack on C1' of the ribose ring either through a concerted or step-wise process, thereby displacing the pyrimidine ring. After *N*-glycosidic bond breakage, the uracilate anion makes a 180° rotation for *C*-glycosidic bond formation

hydrated C-glycoside isomer (F^5U^*) in a time frame similar to the conversion of U to Ψ . Furthermore, HPLC analysis of the nucleotides resulting from treatment of the product RNA with S1 nuclease and alkaline phosphatase showed two more polar products of F^5U , which were shown to be hydrated by mass spectrometry. [25] Subsequent NMR experiments by Miracco and Mueller established that both F^5U products were rearranged similarly to the one seen in the cocrystal structure of TruB with $[F^5U]RNA$. [41]

^{18}O labeling studies

To elucidate the mechanism of the Ψ synthases further, Spedaliere and Mueller conducted labeling experiments with TruB and $[F^5U]TSL$ in $[^{18}O]water$. [42] If the mechanism were to proceed through the formation of a Michael adduct and heating the adduct did indeed lead to the proposed ester hydrolysis, then running the reaction in $[^{18}O]water$ would result in the incorporation of ^{18}O label into the conserved Asp (Figure 1.7). Instead, the label ended in RNA, ruling out ester hydrolysis. [42] The same result held for RluA and TruA. [30, 41] These observations led Mueller and co-workers to propose a scheme to account for the handling of F^5U by all Ψ synthases (Figure 1.8). The Ψ synthase reaction proceeds through either the Michael or acylal to rearranged F^5U , and idiosyncracies of the active site dictate its fate. In some active sites (TruA and RluA, for example), the conserved Asp can reach C6 and make a stable adduct whether it had previously been formed (Michael mechanism) or not (acylal mechanism). In this case, the stable covalent adduct between the conserved Asp and $[F^5U]RNA$ undergoes elimination (rather than ester hydrolysis) upon heating, followed by spontaneous

hydration of the rearranged F⁵U in solution. [30, 41] In other active sites (TruB, for example), the conserved Asp does not form a stable adduct with the pyrimidine, so the rearranged F⁵U is simply released into solution followed by hydration.

Identity of the products of F⁵U

The definitive structural elucidation of the two F⁵U products of TruB was undertaken to provide further mechanistic insight. After isolating the F⁵U* from the action of both TruB and RluA on a suitably large scale, Miracco and Mueller used a myriad of NMR experiments to establish the identity of the products. [43] Their NMR studies revealed that both of the isolated products were dinucleotides (Figure 1.9), [41] which explained an apparent discrepancy in the HPLC behavior for the F⁵U products formed by the reaction of TruB and RluA. [41] The products from the action of TruB had different retention times than the single peak resulting from the action of RluA. Since the RNA substrates differ in the nucleoside following the isomerized U, the different retention times were immediately explained. The single peak for the products of F⁵U from RluA action were simply not resolved by the HPLC conditions. The maintenance of an approximately 3:1 ratio of the two products of F⁵U through the process of enzymatic digestion, isolation, and storage strongly suggested that the two products differed by stereochemical rather than conformational isomerism. [43]

A

B

Figure 1.7: ¹⁸O labeling scheme. A, Ester hydrolysis would result in ¹⁸O incorporation into the conserved Asp. B, Direct hydration of the rearranged product of F⁵U results in labeled F⁵U*.

Figure 1.8: The proposed consistent scheme for the handling of F⁵U in RNA by different Ψ synthases. [41]

The major product was confirmed as the one seen in the cocrystal structure of TruB with [F⁵U]TSL. [40, 43] The minor product proved even more interesting. First, when comparing the chemical shifts of sugar protons in the two products, H^{2'} and C2' of the minor product were deshielded, an indication that the minor product differs from major product at C2' of ribose rather than C6 of the pyrimidine ring. [43] Second, ¹H-¹H Nuclear Overhauser Effect experiments (NOE) showed a strong correlation between H^{2'} and H^{5'}/H^{5''} for the major product that was absent in the minor product, a result which indicated greater separation between H^{2'} and H^{5'}/H^{5''} in the minor product. [43] Third, the strong NOE seen between F⁵ and H^{2'} in the major product was absent in the minor product, and the minor product also lacked a detectable NOE between H^{2'} and H⁶ for minor product that was observed in the major product. [43] These findings along with residual dipolar coupling experiments and density functional theory calculations established the identity of the minor product to be the *arabino* isomer whereas the major product was the *ribo* isomer. These two products, then, differ in stereochemistry at C2' (Figure 1.9). For the *arabino* product to form, epimerization at C2' must occur, which requires deprotonation of C2' to form a glycal intermediate followed by reprotonation of C2' on the opposite face. [43]

major product: *ribo*

minor product: *arabino*

Figure 1.9: The major and minor products of F⁵U* differ in stereo configuration of C2'. [43]

Figure 1.10: The “glycal mechanism” for Ψ formation. The conserved Asp initiates the reaction by deprotonating C2' which leads to a glycal intermediate. After the C-glycoside rearrangement, C2' is re protonated by the conserved Asp.

Figure 1.11: The “glycol mechanism” with F⁵U. Reprotonation from the “bottom” face of the glycal ring results in the observed *arabino* product of F⁵U. [43]

Implications of a glycal intermediate

If a glycal intermediate exists along the reaction pathway, a new mechanistic possibility emerges, the 'glycal' mechanism. (Figure 1.10) Uridine phosphorylase offers a biochemical precedent for glycal intermediate formation in enzymes. [44] Deprotonation of the C2', followed by reprotonation from the "bottom" face would explain the observed *arabino* F⁵U product (Figure 1.11). The acylal mechanism can also account for the formation of an *arabino* product of F⁵U. The decreased nucleophilicity of the 5-fluorouracilate anion effectively increases the lifetime of the acylal intermediate, which is in equilibrium with the oxocarbenium species and the free conserved Asp. The increase in acidity of C2' in the oxocarbenium species facilitates its deprotonation by the conserved Asp to give the glycal intermediate. In such case, reprotonation of the glycal intermediate from the "bottom" face results in an *arabino* product (Figure 1.12). [43]

Because the conserved Asp is the only acidic group in proximity to the sugar ring to effect reprotonation of C2' from the "bottom", the *arabino* product strongly disfavors the Michael mechanism, for the conserved Asp is tied up in an ester bond at the critical time. The alternative protonation directly by solvent (specific rather than general acid catalysis) was ruled out by running the Ψ synthase reaction with [F⁵U]RNA in buffer made with deuterated water¹. [45] However, prior to the findings by Miracco and Mueller that led to the proposal of glycal mechanism, the glycal mechanism was still favored by many. To probe whether the Michael mechanism

¹ This result also rules out exchange of the proton on the enzymic general acid with solvent in the time frame of the reaction.

Figure 1.12: The acylal mechanism recast to emphasize features that can account for the *arabino* product of F⁵U. The boxed manifold exists only for F⁵U because of the increased life time of the oxocarbenium ion that is in equilibrium with the acylal intermediate. [43]

in some form can still accommodate the glycal intermediate, additional mechanistic possibilities were considered. Such considerations in the context of recently published results [46] are presented in the next few sections of this chapter.

Cocrystal structure of RluB with [F⁵U]RNA

While the existence of *arabino* product of F⁵U strongly argues against the Michael mechanism, others continue to champion it. Among them are Stroud and co-workers, who recently reported a cocrystal structure of RluB with [F⁵U]RNA that shows a covalent linkage between C6 of the pyrimidine ring and Tyr-140 (Figure 1.13). [46] Although a covalent adduct with Tyr does not provide direct evidence for the formation of a Michael adduct by the conserved Asp, Stroud and co-workers proposed a ‘modified’ Michael mechanism (Figure 1.14) that is essentially the ‘consistent scheme’ (Figure 1.15) grafted on to the Michael mechanism. The conserved Asp forms a Michael adduct, followed by rearrangement of U to the C-glycoside isomer. The conserved Asp then undergoes elimination to yield the reactive intermediate, which in case of [F⁵U]RNA either gets hydrated (in the cocrystals of TruB and RluA with [F⁵U]RNA) or forms a covalent adduct with Tyr-140 (in the case of RluB). (Figure 1.13)

The mechanism proposed by Stroud and co-workers is based on the assumption that the conserved Asp initially forms a covalent adduct with the pyrimidine ring of [F⁵U]RNA. [46] However, no evidence directly identifies the conserved Asp as the nucleophile that forms the Michael adduct. Although substitution of the conserved Asp abrogates adduct formation, it may be required for the generation of a reactive intermediate rather than direct participation in the

Figure 1.13: A close up view of the active site from the cocrystal structure of RluB and [F⁵U]RNA reported by Stroud and co-workers. A covalent linkage can be seen between the Tyr-140 and C6 of the pyrimidine ring of [F⁵U]RNA. From ref 46.

Figure 1.14: The modified Michael mechanism proposed by Stroud and co-workers. The conserved Asp initially forms a covalent adduct with the C6 of the pyrimidine ring. After rearrangement to the C-glycoside, the conserved Asp undergoes elimination. In the case of [F⁵U]RNA, the F⁵U gets hydrated in solution or, in the case of RluB, forms a covalent adduct with Tyr-140. [46]

adduct. The modified Michael mechanism also fails to explain the observed *arabino* product of F⁵U, which requires epimerization at the C2' of the ribose ring. [43]

The consistent scheme proposed by the Mueller group, on the other hand, still accounts for all observations (Figure 1.15). The Ψ synthases proceed through either the glycal mechanism or the acylal mechanism (re-cast in the wake of *arabino* product) to rearranged F⁵U. In the case of RluB, instead of release into solution and spontaneous hydration, the phenolic –OH of Tyr-140 attacks at C6 of the pyrimidine ring to form the observed covalent adduct, which occurs because the idiosyncracies of the RluB active site allow formation of a stable adduct with Tyr-140. This scenario is supported by the results with *Thermotoga maritima* TruB.

The interesting case of *Thermotoga maritima* TruB (TmTruB)

In an attempt to obtain a covalent adduct of TruB, Huang and co-workers incubated TruB from four different organisms with [F⁵U]RNA, and *T. maritima* TruB (TmTruB) formed a covalent adduct as judged by the appearance of a shifted band on an SDS-PAGE gel (Figure 1.16); heat treatment disrupted the adduct. [47] No such adducts were seen with TruB from *E. coli* (EcTruB), *B. subtilis*, or *S. cerevisiae*. [47] However, the cocrystal structure of TmTruB with [F⁵U]TSL, showed a noncovalent adduct identical to the one seen in case of EcTruB with [F⁵U]TSL. [40, 47] This seemingly disparate behavior made TmTruB an intriguing candidate for further characterization. These studies are described in Chapter 2 of this dissertation.

Figure 1.15: The consistent scheme proposed by Mueller and co-workers with mild revision to account for the *arabino* product of F⁵U and trapping by Tyr-140 of RluB.

The possibility of an active site Tyr forming the Michael adduct

One other scenario that could accommodate a catalytic Michael adduct and the epimerization at C2' would be another nucleophile to form the initial Michael adduct which would leave the conserved Asp free for the deprotonation/reprotonation of C2'. The Ψ synthases show a conserved aromatic amino acid residue, which is a Tyr in five of the six families (it is the tyrosine seen in adduction with [F⁵U]RNA in the RluB cocrystal). However, several lines of evidence argues against the role of Tyr forming a Michael adduct. The fully functional TruD family has nucleophilically incapable Phe residues in this conserved position. [48-50] Additionally, Huang and co-workers have reported that Y76F, Y76L, and Y76A TruB were inactive towards the natural substrate (with U) but do handle [F⁵U]RNA to generate rearranged, hydrated products of F⁵U. [51] If the mechanism proceeds by the forming an initial Michael adduct between Tyr and the pyrimidine ring, the Tyr variants should have left both U and F⁵U unchanged (if the adduct does not form, rearrangement to the C-glycoside should not occur). Finally, the pH profile studies on TruB by Mueller and co-workers suggest that the active site tyrosine residue functions in its *protonated* form to assist *N*-glycosidic bond cleavage of the uridine, presumably by donating either a proton or hydrogen bond to the pyrimidine ring. [26, 52] In either scenario for the active site tyrosine residue, the *N*-glycosidic bond cleavage of F⁵U does not require the assistance of Tyr because the inductive effect of fluorine makes its anion a better leaving group than the anion of uracil.

An *arabino* product of F⁵U must arise from epimerization at C2' after its deprotonation. To probe whether the C2' is deprotonated during the course of the reaction with natural substrate and thus test the operation of the glycal mechanism, stem-loop substrates labeled with deuterium at the C2' position of U were prepared and their rate of reaction compared to those of unlabeled substrates. If the glycal mechanism operates and either deprotonation or reprotonation of C2' is at least partially rate-limiting, replacement of proton on C2' with deuterium should result in a primary kinetic isotope effect and provide definitive evidence for glycal formation. This work constitutes Chapter 4 of this dissertation.

Figure 1.16: A, The interaction of TmTruB and [F⁵U]RNA. [51] An adduct band (indicated by the arrow) was observed when Huang and co-workers incubated TmTruB with [F⁵U]TSL. The increased electrophoretic mobility was attributed to a more compact confirmation that resisted denaturation under the SDS-PAGE conditions. B, A superimposition of the cocrystals of TmTruB and EcTruB with [F⁵U]RNA show the same product of F⁵U and nearly identical positioning of the active site residues.

CHAPTER 2

MECHANISTIC INVESTIGATIONS OF *THERMOTOGA MARITIMA*

TruB

Pseudouridine synthase TruB

The pseudouridine synthases (Ψ synthases) isomerize uridine (U) to its C-glycoside isomer pseudouridine (Ψ), which is the most common modified nucleoside in RNA. [1] Ψ synthases are classified into six families that share no statistically significant global sequence similarity. [18, 53] The pseudouridine synthase TruB isomerizes the universally conserved U55 in the T-arm of tRNA, [28] and homologs of TruB have been found in all organisms. [54-58] Deletion of the *E. coli* TruB (EcTruB) gene does not cause a detectable growth defect. However, *truB* mutants exhibit a competitive disadvantage in extended co-culture with wild-type *E. coli* and a survival defect upon rapid transfer from 37 °C to 50 °C. [59] Deletion of TruB in *Shigella flexneri* reduces the expression of some virulence-associated genes, and disruption of TruB by Tn5 in *Pseudomonas aeruginosa* causes impaired growth and reduced virulence. [60, 61] TruB-catalyzed Ψ 55 modification in *Thermus thermophilus* is essential for the low temperature

adaptation of this extremophile. [12] The ubiquity of *truB* across all eubacteria implies the presence of both TruB and Ψ 55 modification in the common ancestor of eubacteria. [62] Though several homologs of TruB have been studied, crystal structures are available only for EcTruB and *Thermotoga maritima* TruB (TmTruB). [40, 47] TmTruB efficiently handles 17-mer stem-loop substrates corresponding to the T-arm stem loop (TSL) of tRNA. [29, 47, 63] EcTruB is not inhibited upon incubation with RNA containing 5-fluorouridine ([F⁵U]RNA) whereas TruA and RluA appear to form a covalent adduct with [F⁵U]RNA and thus become irreversibly inhibited. [30, 36, 42] Three mechanisms have been proposed (Chapter 1), and they all involve an active site aspartic acid residue (hereafter, the ‘conserved Asp’) that is essential for Ψ synthase activity in all tested cases, which span all six families. [36, 43, 64, 65] The first of these proposed mechanisms—the “Michael mechanism”—involves the conserved Asp nucleophilically attacking the pyrimidine ring at C6 to form a Michael adduct (Figure 1.4). [36]

When TruA is incubated with [F⁵U]RNA, a slower moving adduct band appears on SDS-PAGE gels; this adduct band collapses to separate protein and RNA bands when the sample is heated prior to loading. [36] Furthermore, mass spectrometric analysis revealed that F⁵U in the RNA is hydrated after the adduct is heat-disrupted. These observations led Santi and co-workers to conclude that the conserved Asp of TruA formed a Michael adduct with [F⁵U]RNA, and heat treatment of this adduct led to hydrolysis of the adduct ester bond to leave the F⁵U hydrated (Figure 2.1). When Hoang and Ferré-D'Amaré later obtained a cocrystal structure of TruB with [F⁵U]TSL, they observed not a covalent adduct but a

rearranged hydrated product of F⁵U. This unexpected observation led them to conclude that TruB followed the Michael mechanism through the rearrangement step, at which point reaction stopped. The failure to observe the covalent adduct was ascribed to slow ester hydrolysis over the course of crystal growth and diffraction analysis. [40]

Phannachet and Huang attempted to trap a covalent adduct between TruB and [F⁵U]TSL. They incubated TruB from four different organisms (*E. coli*, *Bacillus subtilis*, *T. maritima*, and *Saccharomyces cerevisiae*) with [F⁵U]TSL, and denaturing PAGE gel analysis revealed that only TmTruB formed an apparently covalent adduct (Figure 1.7). [47] With TmTruB alone, a new band was observed with greater electrophoretic mobility than the protein alone, and the extracted band showed a maximum absorbance at 260 nm, indicating the presence of RNA (nucleic acids show a characteristic absorption maxima at ~260 nm). [47] The TmTruB-RNA adduct was also heat labile. Huang and co-workers grew cocrystals of TmTruB with [F⁵U]TSL and expected to observe a covalent adduct. Despite short crystallization times and low incubation temperatures (48 h at 4 °C), the cocrystal structure of TmTruB with [F⁵U]RNA was identical to that of EcTruB, with no evidence of a covalent linkage between the protein and [F⁵U]RNA and the same rearranged, hydrated product seen in the co-crystal of EcTruB and [F⁵U]RNA (Figure 2.2). [47]. Moreover, the RNA-protein complex recovered from the crystals showed similar gel behavior to that of the purified complex prior to crystallization. [47] Because of their failure to trap a covalent adduct, the Huang group did not speculate as to which mechanistic pathway the Ψ synthases follow.

Spedaliere and Mueller concurrently found that EcTruB is not inhibited by [F⁵U]TSL, instead converting F⁵U into a pair of hydrated C-glycoside isomers (F⁵U*) in a time frame similar to the conversion of U to Ψ. [25] Subsequent NMR experiments reported by Mueller and co-workers confirmed that both F⁵U products were rearranged similarly to the one seen in the cocrystal structure of TruB with [F⁵U]RNA. [41] Spedaliere and Mueller also conducted ¹⁸O labeling studies with EcTruB to probe the putative ester hydrolysis of the Michael adduct. [42] If the mechanism indeed proceeded through a Michael adduct followed by rearrangement and a relatively fast ester hydrolysis step, running the reaction in [¹⁸O]water would result in the incorporation of ¹⁸O into the conserved Asp (Figure 2.3). Mass spectroscopic analysis of the tryptic digestion products of TruB after incubation with [F⁵U]TSL revealed no ¹⁸O incorporation into the conserved Asp but instead showed label directly incorporated into F⁵U*. [42] These studies were later extended to the *E. coli* Ψ synthases RluA, TruA, and TruD, all of which showed the incorporation of ¹⁸O directly into RNA rather than the conserved Asp. [30, 42, 66, 67] These results led to the proposal of a scheme for the hydration step consistent with all observations (Figure 2.4). [42] The F⁵U is rearranged by either mechanism, and then idiosyncrasies in the active site geometry dictate the fate of the initial product. In the case of TruA and RluA, the conserved Asp can form a stable covalent adduct with C6 of the pyrimidine ring, and upon heating, it undergoes elimination followed by spontaneous hydration of the rearranged F⁵U in solution. With TruB, the conserved Asp cannot form a stable adduct, so the rearranged F⁵U is simply released into solution where it undergoes spontaneous hydration. [66]

Figure 2.1: The Michael adduct proposed by Santi and co-workers between the conserved Asp and C6 of the pyrimidine ring. Heat disruption of the adduct results in a hydrated product of F⁵U. [36]

Figure 2.2: An overlay of the cocrystal structures of EcTruB and TmTruB with [F⁵U]RNA and the line drawing of the rearranged, hydrated product of F⁵U seen in the cocrystal structures of TruB with [F⁵U]RNA. [40, 47]

Figure 2.4: Scheme accounting for the formation of apparently covalent adducts by TruA and RluA but not TruB and for the generation of two hydrated products by all three Ψ synthases. [66]

This chapter describes investigation into the behavior of TmTruB towards [F⁵U]RNA. They were undertaken to resolve apparent discrepancies from gel analysis (a covalent adduct appears to form) and X-ray crystallography (no adduct is observed). The results were expected to illuminate the mechanism and also resolve some questions raised by the partial characterization of TmTruB reported by Phannachet and Huang. [47] First, do TmTruB and EcTruB show similar kinetics, and if not, how do they differ? Second, although TmTruB forms an adduct with [F⁵U]TSL as judged by SDS-PAGE analysis, the nature of this adduct as covalent or very tight but noncovalent remained uncertain. Third, if the adduct is covalent, is it the proposed Michael adduct between the C6 of the pyrimidine ring and the conserved Asp, or an adduct with some other active site amino acid residue?

Experimental

Materials

All chemicals, unless specified were purchased from Fisher Scientific (Pittsburgh, PA) or Sigma-Aldrich (Milwaukee, WI). BLR(DE3) pLysS cells were purchased from Novagen (Madison, WI). A DNAPac® PA200 column (4 × 250 mm) was purchased from Dionex (Sunnyvale, CA). A CLYPEUS C₈ 5-μm column (250 × 4.6 mm) was purchased from Higgins Analytical, Inc. (Mountain View, CA), and a Zorbax analytical SB-C18 5-μm column (50 × 4.6 mm) was purchased from Agilent (Santa Clara, CA). A HiPrep 16/60 Sephacryl S-200 HR size exclusion column and Sephadex G-25 resin were purchased from GE Healthcare (Pittsburgh, PA). Ni-NTA superflow resin and QIAprep Spin Mini prep kits were purchased from Qiagen (Chatsworth, CA). S1 nuclease and calf intestinal alkaline phosphatase were purchased from Promega (Madison, WI). Modified trypsin (sequencing grade), endoproteinase Glu-C (sequencing grade), and RNase T1 were purchased from Roche (Indianapolis, IN). QuickChange™ site-directed mutagenesis kits were purchased from Stratagene (La Jolla, CA). [¹⁸O]water (99.7%, v/v) was purchased from Sigma-Aldrich (Milwaukee, WI). Ultra-pure deionized water was obtained using a Millipore® Milli-Q integral system (Billerica, MA) equipped with a 0.2 μm filter. Laemmli buffer (2x) was 120 mM Tris•HCl buffer, pH 6.8, containing SDS (4%, w/v), glycerol (20%, v/v), and bromophenol blue (0.02%, w/v). RNA loading dye (2x) was 95% aqueous formamide, containing bromophenol blue (0.025%, w/v), xylene cyanol (0.025%, w/v), and EDTA (0.5 mM).

Subcloning, overexpression, and purification of wild-type and D39A TmTruB

The recombinant plasmid for TmTruB (pUL390) was prepared by ligating *T. maritima truB* into the expression vector pET-15b (Novagen) so that an N-terminal His₆-tag was fused to expressed TmTruB. The plasmid encoding D39A TmTruB (pUL391) was created by introducing a point mutation into *truB* in pUL390 using the Stratagene QuickChange™ site-directed mutagenesis kit according to the manufacturer's protocols and with the following primers: GGACACGGAGGAACTCTCGCCCCGTTTCGCCTGTGGG (forward), and CCCACAGGCGAACGGGGCGAGAGTTCCTCCGTGTCC (reverse). The inserts in both plasmids (pUL390, pUL391) were verified by DNA sequencing. BLR(DE3) pLysS cells were transformed with pUL390 and pUL391 for the overexpression of wild-type and D39A TmTruB, respectively. Both were purified over Ni-NTA resin using the same protocol used for EcTruB. [64] TmTruB was further purified over a POROS HQ anion exchange column (PE Biosystems) attached to a BioCAD SPRINT FPLC run by Perfusion Chromatography Workstation v3.01. Elution was achieved by the application of a gradient of sodium chloride (0–1.0 M) in 25 mM Tris•HCl buffer, pH 7.5. TmTruB generally eluted at 250–400 mM salt. Fractions bearing TmTruB were tested for RNase contamination, and the RNase-free fractions were heat treated for 15 min at 70 °C followed by centrifugation (18,000g, 15 min) to pellet precipitated proteins. The combined pure fractions of TmTruB were adjusted to 70% nominal saturation with solid ammonium sulfate and stored at 4 °C. Immediately prior to use, aliquots of the ammonium sulfate suspension of TmTruB were diluted with an equal volume

of 25 mM Tris•HCl buffer, pH 7.5, containing sodium chloride (250 mM) and desalted by passage over a column of G-25 resin, equilibrated in the same buffer.

RNA substrates

RNA oligonucleotides were obtained from GE Dharmacon (Lafayette, CO) and deprotected according to the manufacturer's protocol. Following deprotection, RNA was desalted by ultrafiltration using a Centricon-3 device to achieve dilution of small molecules initially present (>1000-fold) and was further purified by reverse phase HPLC over a preparatory C18 column using a gradient of acetonitrile in 25 mM ammonium acetate buffer, pH 6.0. RNA-bearing fractions were taken to dryness *in vacuo* in a Savant DNA120 speedvac (Thermo Electron), redissolved in RNase-free water, and stored as aliquots at -80 °C until further use.

Digestion and MALDI-MS analysis of TmTruB and TmTSL

TmTruB. Solutions of wild-type or D39A TmTruB (50 µg) were incubated for 15 min at 94 °C to denature the protein. The precipitate was then pelleted by centrifugation (18,000g, 15 min), and the protein pellet was suspended in 25 mM sodium phosphate buffer (100 µL), pH 7.8, containing trypsin (0.01 mg/ml), endoproteinase Glu-C (0.02 mg/ml), and acetonitrile (10% v/v). This mixture was incubated for 12 h at 25 °C. An aliquot (10 µL) was drawn up into ZipTip_{C18} pipetter tip (Millipore, Bedford, MA) and then expelled; the bound peptides were washed (10 × 10 µL) with aqueous trifluoroacetic acid (0.1% v/v) and eluted with Cl-CCA matrix solution (5 µL), which was 4-chloro- α -cyanocinnamic acid (6.24 mg/ml) in 70% aqueous acetonitrile containing trifluoroacetic acid (0.1% v/v). The ZipTip

eluate (1 μ L) was spotted on a MALDI sample plate, air dried, and analyzed on a Voyager DE-Pro MALDI-TOF instrument (PE Biosystems, Foster City, CA). Spectra were acquired in positive reflectron mode with an extraction delay time of 200 ns and 400 laser shots per spectrum. Calibration was achieved using a 1:1:2 mixture of Bradykinin fragment 1-7 (757.399 m/z), fragment 18-39 of ACTH (2465.1989 m/z), and the oxidized β -chain of insulin (3494.6513 m/z) purchased from Sigma-Aldrich (St. Louis, MO).

RNA. An aliquot of RNA (10 μ L, 100 μ M) was diluted into RNase-free water (40 μ L) to which RNase T1 (2 μ L, 200 U) or RNase A (2 μ L, 200 U) was added and incubated for 1 h at 37 °C. Following this, alkaline phosphatase (5 μ L, 5 U) was added to the digestion mixture, which was additionally incubated for 3 h at 37 °C. An aliquot (3 μ L) of the digest was mixed with the 3-HPA matrix solution (3 μ L), which was 3-hydroxypicolinic acid (3-HPA; Fluka, Milwaukee, WI; 10 mg/ml) in 50% aqueous acetonitrile. The sample was spotted on a MALDI plate, air dried, and analyzed. Mass spectra were acquired either in positive or negative reflectron mode; calibration was achieved by a conventional 3-point method using a mixture of standard oligonucleotides: TTTGCTT (2076.37 monoisotopic mass), T₁₀ (2978.49), and T₁₅ (4498.721) purchased from GE Dharmacon. Data was analyzed with mMASS data analysis software, version 5.5.1. [68]

Kinetic analysis of TmTruB

Standard reaction buffer was 25 mM Tris•HCl buffer, pH 7.5, containing sodium chloride (250 mM) and DTT (5 mM). The reaction mixtures (1200-4000 μ L) were standard reaction buffer containing TmTSL (50-2500 nM). After pre-

incubation for 3 min at 58 °C, reactions were initiated by the addition of a small volume (<6 µL) of TmTruB (to 1.5 nM). Aliquots (300-1000 µL) were removed at various time intervals (30, 60, 90, and 120 s) and quenched by extracting TmTruB into an equal volume of chilled (4 °C) phenol saturated with 10 mM Tris•EDTA buffer, pH 4.5. After a second extraction with 1:1 phenol:chloroform saturated with the same buffer, the RNA was precipitated with ethanol, pelleted by centrifugation, and air-dried. The pelleted RNA was redissolved in standard reaction buffer (100 µL), passed through a Corning Costar™ spin filter (0.22 µm), and analyzed by HPLC over a DNAPac® PA200 column connected to an Agilent 1100 HPLC system equipped with an IC-3000 binary pump (Dionex, Sunnyvale, CA). RNA samples were eluted using a gradient of sodium chloride (100-1.25 M) in 100 mM Tris•HCl buffer, pH 9.0, by use of the following program (the first number is the percentage of high salt buffer, which is 100 mM Tris•HCl buffer, pH 9.0, containing sodium chloride (1.25 M); the second number is the elapsed time in minutes): 0, 26.4; 1, 26.4; 26, 57.6; 26, 80; 27, 80; 27, 26.4; 40, 26.4.

Analysis of the TmTruB-[F⁵U]TmTSL adduct

TmTruB and [F⁵U]TmTSL were incubated in standard reaction buffer at 58 °C. After 3 h, the sample was either heated to 94 °C and held for 5-15 min or loaded directly onto the gel. The SDS-PAGE gels (10%) were stained with Coomassie™ blue, and the urea-PAGE gels (12%, 7 M urea) were first stained with SYBR® Gold stain (to visualize RNA) followed by Coomassie™ blue (to visualize protein). Occasionally, RNA used in adduct studies was visualized by virtue of the

fluorescence of an attached fluorescein (FI) moiety by purchasing RNA with a 5'-FI label.

The time course for the formation of [F⁵U*]TmTSL was obtained by incubating TmTruB (5 µM) with [F⁵U]TmTSL (10 µM) in standard reaction buffer at 58 °C. Aliquots of the reaction mixture (20 µL) were withdrawn at regular time intervals and immediately quenched by mixing with 2x Laemmli buffer or 2x RNA loading dye (20 µL) and incubating at 94 °C for 5 min. After cooling the tubes on ice for 5 min, samples were analyzed by SDS-PAGE and urea-PAGE. Aliquots of the reaction mixture (15 µL) were also withdrawn at regular time intervals to test for the formation of [F⁵U*]TmTSL by HPLC analysis. The withdrawn aliquots were immediately quenched by the extraction of protein into 1:1 phenol:chloroform as described above. The RNA was precipitated from the separated aqueous phase with ethanol, pelleted by centrifugation, air-dried, redissolved in water (100 µL), and filtered (0.22 µm) for HPLC analysis.

Size exclusion studies

TmTruB and size standards were diluted into either 25 mM Tris•HCl buffer, pH 7.5, containing sodium chloride (250 mM) or 50 mM sodium phosphate buffer, pH 7.0, containing sodium chloride (150 mM) to a final concentration of 2-5 mg/ml and loaded on to a HiPrep Sephacryl S-200 HR (16 × 600 mm) size exclusion column fit to a BioCAD SPRINT FPLC run by Perfusion Chromatography Workstation v3.01; elution was accomplished with the same buffer flowing at 0.4 mL/min. For studies with the adduct, TmTruB (50 µM) and [F⁵U]TmTSL (50 µM) were initially incubated in standard reaction buffer for 3 h at 58 °C. Following

analysis by urea-PAGE to assess adduction, the sample (without dilution) was injected onto the Sephacryl S-200 column and eluted isocratically with standard reaction buffer.

¹⁸O labeling studies

To allow pre-equilibration of water molecules in the active site with bulk solvent, TmTruB (20 μM) was incubated either in standard reaction buffer (250 μL) or in the same buffer (250 μL) containing 50% [¹⁸O]H₂O for 5 min at 58 °C. The reaction was initiated by adding a small aliquot (5.6 μL) of [F⁵U]TmTSL (40 μM). After 3 h, an aliquot (60 μL) of the reaction mixture was analyzed by urea-PAGE and SDS-PAGE to assess adduct formation, and another aliquot (5 μL) of the reaction mixture was diluted into S1 nuclease digestion buffer (95 μL), which is 30 mM sodium acetate buffer, pH 4.6, containing sodium chloride (50 mM), zinc chloride (10 mM), and glycerol (5%, v/v). S1 nuclease (0.5 μL, 50 U) was added, and the mixture was incubated for 1 h at 37 °C; the digest was then incubated for 5 min at 94 °C followed by incubation on ice for 5 min. Subsequently, a fresh aliquot of S1 nuclease (1 μL, 100 U) and alkaline phosphatase (3 μL, 3 U) were added, and the mixture was incubated for 3 h at 37 °C. The digest was then analyzed over an SB-C18 analytical column connected to Beckman Coulter System Gold HPLC (Indianapolis, IN) equipped with a model diode array detector.

For the unlabeled reaction, the remainder of the reaction mixture (185 μL) was incubated for 15 min at 94 °C then placed on ice for 5 min. Precipitated

TmTruB was pelleted by centrifugation (18,000g, 15 min). The supernatant was removed, and residual protein was extracted with 1:1 phenol:chloroform as described above. The RNA was precipitated with ethanol, and the resultant pellet was washed with cold ethanol (70%, v/v), air-dried, and dissolved in RNase-free water (100 μ L). To this solution, RNaseT₁ (3 μ L, 300 U) was added, and the mixture was incubated for 1 h at 37 °C. Following this, alkaline phosphatase (5 μ L, 5 U) was added to the digestion mixture, which was incubated for 3 h at 37 °C. An aliquot (3 μ L) of the resulting dephosphorylated oligonucleotides was mixed with 3-HPA matrix solution (3 μ L), spotted onto MALDI plate, and air dried for acquisition of mass spectra. Another aliquot (0.5 μ L) of the digest was mixed with the 3-HPA matrix solution (0.5 μ L) made with 50% [¹⁸O]water, and mass spectra were acquired. Finally, an aliquot (3 μ L) of the digest was diluted 1:1 with [¹⁸O]water and incubated for 3 h at 37 °C before mixing with 3-HPA matrix solution (3 μ L) and analysis by mass spectrometry.

A part of the pellet (TmTruB) from the unlabeled reaction was suspended in 25 mM sodium phosphate buffer (50 μ L), pH 7.8. To this, trypsin (1 μ g) and endoproteinase Glu-C (2 μ g) were added, and the mixture was incubated for 12 h at 25 °C. An aliquot (10 μ L) of the digestion mixture was desalted using a ZipTip_{C18} as described above, and the bound peptides were eluted in 70% aqueous acetonitrile containing trifluoroacetic acid (0.1% v/v). The ZipTip eluate (1 μ L) was mixed with CI-CCA matrix solution (1 μ L) spotted on a MALDI sample plate, air dried, and analyzed. An aliquot of the ZipTip-purified sample (3 μ L) was mixed with CI-CCA matrix solution prepared in 50% [¹⁸O]water and analyzed. The rest of the

pellet from the unlabeled reaction was suspended in sodium phosphate buffer, pH 7.8, containing [^{18}O]water (50%, v/v) and digested with trypsin/endonuclease Glu-C (1 μg /2 μg) as described above. The resulting peptide mixture was desalted and concentrated using a ZipTip_{C18}, and an aliquot of the eluate (1 μL) was mixed with CI-CCA matrix solution (1 μL) and analyzed.

For the labeled reaction, the ^{18}O content of the buffer was either maintained at 50% or diluted to 10% prior to heat disruption of the adduct. Following heat disruption, the protein and RNA were separated, digested, and analyzed as described for the unlabeled reaction. For pre-incubation studies with it, [F^5U^*]TmTSL was prepared by incubating TmTruB (45 μM) with [F^5U]TmTSL (70 μM) in standard reaction buffer (150 μL) for 3 h at 58 °C. Following this, RNA was isolated as described above and purified over the DNAPac PA200 column. Purified [F^5U^*]TmTSL (10 μM) was then pre-incubated in standard reaction buffer containing [^{18}O]water (50%, v/v), and TmTruB (10 μM) was added immediately prior to heat-treating the mixture for 15 min at 94 °C. Following this, RNA and protein were separated, digested, and analyzed as described above.

Results

Subcloning, overexpression, and purification of TmTruB

The expression vectors pUL390 and pUL391 were created to encode wild-type and D39A TmTruB, respectively, with an N-terminal His₆-tag. Both proteins were overexpressed by standard methods, [64] and TmTruB was purified to near homogeneity by nickel affinity chromatography followed by anion exchange chromatography and heat treatment (Figure 2.5). The final step was possible because TmTruB is thermostable whereas the impurities (*E. coli* cellular proteins) are denatured by heat and then easily removed by centrifugation. Initially, the concentrations of TmTruB were determined by biuret assay [69] and the method of Gill and von Hippel [70], which uses A_{280} of denatured protein and a calculated sequence-dependent extinction coefficient. These values were in reasonable agreement and used to determine ϵ_{280} for the *native* protein and a conversion factor for the Bio-Rad protein assay with bovine serum albumin as the standard. [71] Subsequently, A_{280} or the Bio-Rad assay were used to determine the concentration of TmTruB. For long-term stability, pure fractions of TmTruB were pooled and concentrated to 2-5 mg/ml, and ammonium sulfate was added to nominal 70% saturation. Of several storage conditions tested, this one was found to be superior as judged by periodic activity assays. [72] Under these conditions, TmTruB retained >80% activity over six months.

Kinetic characterization of TmTruB

The kinetic characterization of TmTruB had not been previously reported, so the first goal was to determine k_{cat} and K_{m} for comparison with those of its mesophilic homolog EcTruB. In order to establish a convenient and informative assay, several conditions had to be optimized, including quench methodology, temperature, substrate, and reaction buffer.

Quench conditions

Most fundamentally, a discontinuous assay requires an efficacious quenching of the reaction, so several quench conditions were scouted. Heat was excluded as an efficient quencher because *T. maritima* is an extremophile that grows optimally at 65-90 °C. [73] Quench by the extraction of protein with phenol was found to be effective and convenient. The efficacy of phenol quench was verified by analyzing time points for each assay immediately after addition of TmTruB to initiate the reaction. HPLC analysis of these time points showed <1% conversion of substrate (TmTSL^U) to product (TmTSL^Ψ).

Reaction temperature and choice of substrate

Generally, an assay temperature should be in close proximity to the growth optimum for the host organism, which is 60-85 °C for *T. maritima*. Furthermore, since the RNA substrate needs to adopt its folded conformation to be handled by TmTruB, the assay temperature must be at least several degrees below the

melting temperature (T_m)² of the substrate to assure a preponderance of folded RNA. Three different TSL substrates from *E. coli*, *T. maritima*, and *T. thermophilus* tRNAs were scouted for this purpose (Figure 2.6). The TSL from *T. maritima* tRNA^{Phe} (TmTSL^U) was chosen because it has a suitable melting temperature (T_m = 68–72 °C) and represents the exact sequence of one TmTruB substrate (tRNA^{Phe}). [74] The optimal reaction temperature was found by incubating TmTruB (25 nM) with TmTSL^U (1 µM) at various temperatures (4–85 °C) in standard reaction buffer for 1 h followed by measurement of the amount of product (TmTSL^Ψ). To achieve that end, the RNA was digested with S1 nuclease and alkaline phosphatase. The resulting nucleosides were separated by HPLC over a C₁₈ column with quantification by A₂₆₀ normalized using ϵ_{280} of the nucleosides (Figure 2.7, panel A). For the reactions run between 50 and 85 °C, complete conversion was observed after 1 h. A reaction temperature of 58 °C was chosen because it was convenient and well below the melting temperature of TmTSL^U.

RNA digestion

The measurement of the concentration of TmTSL^Ψ with minimal manipulation and maximal sensitivity would be best. The preliminary assays described above relied on digestion of TSL *E. coli* tRNA^{Phe} to its component nucleosides and their quantitation. Although effective, this method requires digestion, and the sensitivity is limited by the absorbance of Ψ. The greater absorbance of intact TSL (due to the contribution of all 17 component nucleosides)

² The melting temperature (T_m) is the temperature at which half of the RNA population is in the folded conformation (hairpin loop) and half is denatured.

enhances sensitivity, and the absence of a digestion step is clearly more convenient. Intact *E. coli* TSL^U, however, cannot be separated from *E. coli* TSL^Ψ despite myriad attempts with a wide array of elution conditions from numerous column matrices. Digestion with RNase A or RNase T1 places the product nucleoside in a smaller oligonucleotide, which maintains some advantage in sensitivity (although still requiring an 'extra' manipulation) and should allow more facile separation of substrate and product since the difference between them is now in a context less likely to overwhelm it. However, the oligonucleotide with Ψ after digestion of *E. coli* TSL with either RNase was not readily separated from its parent with U.

Fortunately, intact TmTSL proved more amenable to the needs of the assay. In addition to the reasons stated above for choosing it as the standard substrate, it was also recommended by the ready separation of TmTSL^Ψ from TmTSL^U by chromatography over a mixed hydrophobic/anion exchange column (DNAPac PA200). Elution by a gradient of increasing salt yields baseline separation of the intact substrate and product stem-loop RNAs (Figure 2.7, panel B).

Reaction buffer and enzyme concentration

Phosphate buffer and Tris•HCl buffers with pH ranging from 7.0-8.5 and variable salt concentrations (100-500 mM sodium chloride or potassium chloride) were considered for the assay. TmTruB was considerably slower (>5 fold) in phosphate buffer in accord with previous results for other Ψ synthases, [30] so Tris•HCl buffer was chosen for the assay. To test the effect of salt concentration,

TSL from *Escherichia coli* tRNA^{Phe} (TSL)

TSL from *Thermus thermophilus* tRNA^{Phe}
(TtTSL)

Figure 2.7: A, Endpoint (1 h) assays of the activity of TmTruB (25 nM) incubated with TmTSL^U (1 μM) at different temperatures. B, Time course for the reaction of TmTSL^U (1 μM) catalyzed by TmTruB (5 nM) at 58 °C.

TmTruB (1.5-25 nM) was incubated with TmTSL (500-5000 nM) in 25 mM Tris•HCl buffer, pH 7.5, containing sodium chloride (125-500 mM). Aliquots of these reactions were withdrawn at various time intervals, and product-bearing fractions were measured for TmTSL^Ψ formation. At low salt concentration (125 mM sodium chloride), the reaction was extremely fast even at low concentrations of TmTruB (complete conversion occurring within <1 min). TmTruB (1.5 nM) was conveniently assayed at a somewhat high salt concentration (250 mM), which was adopted as the standard reaction buffer.

Steady state kinetic parameters for TmTruB

With the various considerations addressed, the final assay described in the Experimental section was used to determine k_{cat} and K_{m} for TmTruB. Rates of TmTSL^Ψ formation at variable substrate concentrations (Figure 2.8, panel A; Table 2.1) were fit to the Briggs-Haldane equation to yield $k_{\text{cat}} = 0.67 \pm 0.02 \text{ s}^{-1}$ and $K_{\text{m}} = 1112 \pm 58 \text{ nM}$.

Adduct formation between TmTruB and [F⁵U]TmTSL

To probe adduct formation, TmTruB (2.5-10 μ M) was incubated with [F⁵U]TmTSL (2.5-10 μ M) in different ratios (1:1, 1:2, 2:1) in standard reaction buffer for 3 h at 58 °C and were analyzed by SDS-PAGE (10%) and urea-PAGE (12%, 7M urea) gels (Figure 2.9). The gel analysis revealed a new, faster-moving adduct band that stained for both protein and RNA. SDS-PAGE analysis showed only a modest adduction (~33%) even when TmTruB (2.5 μ M) was incubated with excess [F⁵U]TmTSL (5 μ M). With urea-PAGE, a substantial amount of free TmTruB remained despite a consistently higher level of adduction (78%, Figure 2.9), although substantial variation in the measured level of adduction was observed across replicate trials (Figure 2.10).

To assess product formation, TmTruB (2.5 μ M) was incubated with [F⁵U]TmTSL (5 μ M) for 3 h at 58 °C. The RNA was treated with S1 nuclease and alkaline phosphatase, and the resulting nucleosides were analyzed by reverse phase HPLC. Peaks identical in retention time to the products of F⁵U from the action of EcTruB (F⁵U*) confirmed the identity of the products from the action of TmTruB. To probe its inhibition by [F⁵U]RNA, [F⁵U]TmTSL (5 μ M) was pre-incubated with TmTruB (2.5 μ M) in standard reaction buffer (50 μ L) for 3 h at 58 °C. A small aliquot (2.4 μ L) of the mixture was assayed by incubation with TmTSL^U (5 μ M) in standard reaction buffer (300 μ L). Aliquots of this reaction withdrawn at various times and analyzed by HPLC revealed a substantial reduction (~8 fold) in the rate compared to untreated TmTruB (Figure 2.11).

Figure 2.10: A-E, Replicates of adduction trials with TmTruB (40 μM) and [F⁵U]TmTSL (20 μM) and analysis by urea-PAGE (15%, 7M urea). F, Adduction trial with TmTruB (20 μM) and [F⁵U]TmTSL (20 μM). The quantitation of adduct, to free protein, and free RNA is summarized in Table 2.2. 5'-Fluorescein-labeled [F⁵U]TSL was used in the experiments shown in panels A and B; SYBR Gold was used to stain RNA in panels C-F.

Table 2.2: Changing ratios of adduct to free protein and free RNA were observed on urea-PAGE gels (Figure 2.10; 15%, 7M urea) for replicates of TmTruB (40 μ M) and [$F^{5}U$]TSL (20 μ M) incubations.

Size exclusion chromatography

Size exclusion chromatography separates molecules based on their size (molecular weight, M_r) and shape. The elution of a certain sample is usually characterized by the partition coefficient (K_{av}), which is related to the size of the molecule (Figure 2.12). [75] Standard proteins can be used to create a calibration curve with K_{av} plotted against $\log(M_r)$ to determine the apparent M_r of the protein of interest. [75]

One possible explanation for substoichiometric adduct formation is a distribution between reactive and unreactive states of TmTruB. In particular, the unbound protein band on denaturing gels could arise from inactive dimer (or a higher multimeric form) of TmTruB. To probe this possibility, M_r for TmTruB was assessed by size exclusion chromatography in both standard reaction buffer and in 50 mM sodium phosphate buffer, pH 7.0, containing sodium chloride (150 mM) (as recommended by the column manufacturer). Molecular weight standards were used to generate a calibration curve with which M_r for TmTruB was calculated based on its elution volume, V_e (Figure 2.14). In phosphate buffer, the apparent molecular weight of TmTruB (40.5 kDa) does not differ markedly from the theoretical monomeric value (37.6 kDa) (Figure 2.12, panel A), but the value in standard reaction buffer was distinctly lower (25.0 kDa) (Figure 2.13, panel B).

Size exclusion studies were also performed on the TmTruB-[F⁵U]RNA adduct, which was prepared by incubating TmTruB (50 μ M) with [F⁵U]TmTSL (50 μ M). The free protein, free RNA, and adduct displayed very similar

Theoretical chromatogram of a high resolution fractionation.

$$K_{av} = \frac{V_e - V_0}{V_t - V_0}$$

where,

V_e = elution volume for the protein

V_0 = column void volume = elution volume for Blue Dextran

V_t = total bed volume

Figure 2.12: Theoretical trace for size exclusion chromatography. From GE Healthcare manual 18-1022-18.

Figure 2.13: Overlay of traces from size exclusion chromatography of standards and TmTruB. A, Run in phosphate buffer. B, Run in Tris buffer.

Figure 2.14: Plot of K_{av} versus $\log(M_r)$ for standards and TmTruB. A, Run in phosphate buffer. B, Run in Tris buffer.

displayed very similar V_e (62 mL, 64 mL, and 58 mL, respectively; Figure 2.15), making it very difficult to differentiate the adduct from free RNA and protein. Denaturing PAGE analysis of the eluted fractions (42-70 mL) from the run with the adduct showed free TmTruB, free RNA, and the adduct, which suggests co-elution (Figure 2.16).

Time course for the formation of [F⁵U*]TmTSL

The size exclusion chromatography results seem to disfavor the hypothesis that an inactive TmTruB dimer accounts for the free protein seen by denaturing PAGE, which raises the possibility that some fraction of TmTruB is simply incapable of interacting with [F⁵U]RNA because of some unknown post-translational event. To address this question, TmTruB (5 μ M) was incubated with an excess of [F⁵U]TmTSL (50 μ M), and the ratio of adduct to free protein was monitored over time by urea-PAGE. This analysis revealed surprisingly fast adduct formation, with ~50% of TmTruB in the adduct form by the time first aliquot was withdrawn (5 min), the ratio of adduct to free protein and RNA slowly increased over the course of 3 h (Table 2.3; Figure 2.16). In apparent contradiction, the HPLC analysis revealed >90% conversion of [F⁵U]TmTSL into its hydrated product, a level that held constant and which requires more than 9 turnovers by each active site; the first turnover occurred within 5 min (Figure 2.17).

¹⁸O labeling studies

Characterization of TmTruB and [F⁵U]TmTSL by mass spectrometry

Monitoring ¹⁸O incorporation into RNA or protein by mass spectrometry requires a clear window in the mass spectrum. An overlap of the peptide containing Asp-39 with other peptides would interfere with the detection of ¹⁸O incorporation, and the digestion of product RNA provides isotopic resolution and improved sensitivity.

Different proteolytic enzymes and digestion conditions were tried to get peptides containing the conserved Asp (Asp-39) in a clear window. The proteolytic digestion of thermophilic TmTruB proved extremely difficult as the enzyme resisted proteolysis by trypsin, chymotrypsin, endoproteinase-GluC, or pepsin under conventional conditions. Denaturation of TmTruB prior to proteolytic digestion using guanidinium chloride, trichloroacetic acid, or urea also failed to deliver suitable digestion. Ultimately, the combination of trypsin and endoproteinase Glu-C (hereafter “trypsin/Glu-C”) yielded two peptides that matched the expected mass of proteolytic fragments containing Asp-39. The identity of these peptides could not be confirmed by MS/MS methods, probably due to inadequate sensitivity and the hydrophobicity of these peptides. [76] To confirm the identity of the putative peptides containing Asp-39, D39A TmTruB was overexpressed, purified, and subjected to trypsin/Glu-C digestion. The expected shift of 39 Da for the peptides confirmed their identity (Figure 2.18). For [F⁵U]TmTSL, digestion with RNase T1³

³ RNase T1 specifically cleaves RNA after the nucleotide G.

delivered the oligonucleotide containing F⁵U in a clear mass spectral window (U[F⁵U]CG, 1219.23 monoisotopic mass; Figure 2.20, panel A). For the trypsin/Glu-C digestions, sequence coverages of 73% and 89% were observed, respectively, for wild-type TmTruB (Table 2.4) and D39A TmTruB (Table 2.5).

Controls for ¹⁸O exchange

Control experiments were run to exclude the exchange of the ¹⁸O label between Asp-39 and the solvent molecules on the timescale of reaction workup and mass spectral acquisition. An aliquot (10 µL) of TmTruB digested with trypsin/Glu-C was mixed with [¹⁸O]water (10 µL) and incubated for 3 h at room temperature prior to analysis. Also, an aliquot (3 µL) of the trypsin/Glu-C digestion of TmTruB was mixed with CI-CCA matrix solution (3 µL) made with [¹⁸O]water (50%, v/v) and analyzed. These control experiments showed no incorporation of ¹⁸O into the peptides containing Asp-39, thereby excluding the possibility of oxygen exchange with solvent under the reaction conditions and analysis. To ensure the isotopic content of the [¹⁸O]water and assure that methods are sufficiently sensitive to detect ¹⁸O incorporation, TmTruB was digested with trypsin/Glu-C in 25 mM sodium phosphate buffer, pH 7.8, containing [¹⁸O]water (50%, v/v) and analyzed. As expected, ¹⁸O was incorporated into the C-termini of proteolytically-generated peptides (Figure 2.19, panel C).

Similar control experiments were performed with [F⁵U]TmTSL. To eliminate the possibility of ¹⁸O exchange with solvent on the timescale of RNA isolation and workup, RNase T1-digested and dephosphorylated [F⁵U*]TmTSL (10 µL) was

mixed with [^{18}O]water (10 μL), incubated for 3 h at room temperature, and analyzed. To eliminate the possibility of ^{18}O exchange between solvent and RNA during mass spectral acquisition, an aliquot (3 μL) of the RNase T1-digested and dephosphorylated [F^5U^*]TmTSL was mixed with 3-HPA matrix solution (3 μL) made with [^{18}O]water (50%, v/v). The mass spectra showed no incorporation of ^{18}O into the F^5U^* containing oligonucleotide (or any others).

TmTruB

Once the control experiments delivered satisfactory outcomes, TmTruB (10 μM) was incubated with [F^5U]TmTSL (40 μM) in standard reaction buffer (250 μL) made with [^{18}O]water (50%, v/v) for 3 h at 58 $^{\circ}\text{C}$, and the reaction mixture was heated for 15 min at 94 $^{\circ}\text{C}$ to disrupt the adduct. After centrifugation, the supernatant was removed, and the pelleted TmTruB was resuspended, digested with trypsin/Glu-C, mixed with CI-CCA matrix solution, and analyzed. If ester hydrolysis occurs and ^{18}O gets incorporated into the Asp-39 containing peptide, the isotopic composition for this peptide should match that of the reaction buffer (50% ^{18}O). Instead, the mass spectrum for this labeled reaction (Figure 2.19, panel B) is identical to the reaction run in unlabeled buffer (Figure 2.19, panel A).

Figure 2.19: Partial mass spectra of trypsin/Glu-C digestion peptides for TmTruB showing $^{33}\text{VGHGGTLPFACGVLIIGVNNQGR}^{55}$ (2381.1 mono-isotopic mass). A, Reaction and disruption in unlabeled buffer. B, Reaction and disruption in buffer containing $[^{18}\text{O}]\text{water}$ (50%, v/v). C, Reaction and disruption in unlabeled buffer with proteolysis in buffer containing $[^{18}\text{O}]\text{water}$ (50%, v/v). The line diagrams to the right of spectra represent theoretical isotopic intensities.

[F⁵U*]TmTSL

Prior to heat-disrupting the adduct, the ¹⁸O content of the reaction was either maintained at 50% (v/v) or diluted to achieve 10% (v/v) final composition. Following 15 min at 94 °C, the RNA was freed of denatured TmTruB by centrifugation, digested with RNase T1, dephosphorylated with alkaline phosphatase, and analyzed by mass spectrometry. If the oxygen atom in F⁵U* comes directly from solvent, the extent of ¹⁸O incorporation would mirror the isotopic composition of the buffer (50% or 10%).

For the reaction run in labeled buffer, the RNaseT1 digests of both samples (50% and 10%; Figure 2.20, panel C and D) explicitly show that ¹⁸O is incorporated into RNA directly from the solvent. However, these experiments did not clarify the timing of ¹⁸O incorporation—whether it is during the formation or the disruption of the adduct. The reaction run in unlabeled buffer and heat-disrupted in buffer containing [¹⁸O]water (50%) (Figure 2.20, panel E) shows that ¹⁸O incorporation depends on the composition of the buffer during the disruption step. However, given the 1:4 TmTruB:[F⁵U]TmTSL reaction stoichiometry and based on 50% adduction as judged by the urea-PAGE analysis of this sample (data not shown), only 1/8 of the total RNA should incorporate ¹⁸O. In other words, the percentage of ¹⁸O incorporation was higher (50%) than expected (12.5%).

To make sure the unusual amount of ¹⁸O incorporation into RNA was not introduced by an error in the calculation of relative isotopic intensities, the RNase T1 digest of [F⁵U*]TmTSL from the labeled reactions (50% and 10% ¹⁸O) was

Figure 2.20: Partial mass spectra of the RNase T1-digested $[F^5U]TmTSL$ showing the oligonucleotide containing the F^5U ($U[F^5U]CG$; $1217.17 m/z_{pred}$). A, $[F^5U]TmTSL$. B, $[F^5U^*]TmTSL$ from reaction in unlabeled buffer. C, $[F^5U^*]TmTSL$ from reaction in buffer containing $[^{18}O]water$ (50%, v/v) followed by dilution to 10% ^{18}O prior to digestion. E, $[F^5U^*]TmTSL$ from reaction in unlabeled buffer and disruption in buffer containing $[^{18}O]water$ (50%, v/v).

was purified using reverse phase HPLC, and the fractions bearing F⁵U*-containing oligonucleotide were pooled, concentrated, and analyzed. This additional step of purification resulted in mass spectra with greater intensity and better isotopic resolution. However, the calculated isotopic composition of the F⁵U* matched the results prior to the HPLC purification, suggesting that the observed results were not artifactual.

TmTruB can handle [F⁵U*]TmTSL

For the adduction reaction run in unlabeled buffer and heat disrupted in standard reaction buffer made with [¹⁸O]water (50%, v/v), the unexpectedly high incorporation of ¹⁸O into F⁵U* (Figure 2.20, panel E), is possible only if TmTruB is able to handle [F⁵U*]TmTSL in solution. In other words, not only does TmTruB handle [F⁵U]TmTSL, but it can also dehydrate and rehydrate F⁵U*, thereby altering its isotopic composition to match that of the solvent. For this to happen, TmTruB must be active toward [F⁵U*]TmTSL during the initial stages of heating to disrupt the adduct. To test this theory, [F⁵U*]TmTSL was incubated in labeled buffer, and TmTruB was added shortly before heat treatment followed by the isolation of RNA, digestion, and analysis. The mass spectrum showed ¹⁸O incorporation (50%) into F⁵U* (Figure 2.21), indicating that TmTruB is able to handle [F⁵U*]TmTSL.

Discussion

Kinetic characterization of TmTruB

An effective assay was developed for the kinetic characterization of TmTruB. The kinetic parameters, $k_{\text{cat}} = 0.67 \pm 0.02 \text{ s}^{-1}$ and $K_{\text{m}} = 1112 \pm 58 \text{ nM}$ reveal TmTruB at 58 °C to be a better catalyst than EcTruB and RluA at 37 °C (Table 2.7). [29, 30, 64] These k_{cat} and K_{m} values were obtained at a relatively high salt concentration (250 mM). At a salt concentration (125 mM sodium chloride) similar to that used for the assay of EcTruB and RluA (100 mM ammonium chloride), TmTruB had such greater activity that it proved impractical to determine the initial velocities.

Adduct formation between TmTruB and [F⁵U]TmTSL

The formation of a covalent adduct between TmTruB and [F⁵U]TmTSL was explored by denaturing PAGE and HPLC analysis. The SDS-PAGE and urea-PAGE gels showed a new band that contained both protein and RNA. Also, TmTruB pre-incubated with [F⁵U]TmTSL showed a continuing decrease in catalytic activity that suggests TmTruB gets increasingly inhibited upon exposure to [F⁵U]RNA. However, TmTruB could never be completely driven into the adduct as judged by denaturing PAGE (Figure 2.9). This failure to achieve complete adduction raises the question of whether the adduct is noncovalent, although it seems implausible for a noncovalent adduct to survive the denaturing conditions of SDS and urea-PAGE gels. This behavior of TmTruB (partial adduction) could arise for two reasons. First, TmTruB may need to adopt a specific conformation

Table 2.7: Kinetic parameters obtained for TmTruB in comparison to those for EcTruB [29, 64] and RluA. [30]

Enzyme	k_{cat} , s ⁻¹	K_m , nM
TmTruB	0.67 ± 0.02	1112 ± 58
EcTruB	0.24^a	800^a
	0.12 ± 0.01^b	146 ± 14^b
RluA	0.067 ± 0.003	308 ± 66

^aWith TSL [29]

^bWith full length tRNA transcript [64]

to bind RNA, and only a part of the protein exists in such a conformation at any given time. 2) Part of TmTruB (the free protein seen on gels) may exist as a dimer or some other multimeric form of TmTruB that cannot bind RNA. To assess whether TmTruB exists as a dimer, size exclusion chromatography was used to measure the apparent M_r for TmTruB. These studies surprisingly revealed different estimations of M_r for TmTruB in phosphate buffer (40.5 kDa) and Tris•HCl buffer (25.0 kDa) compared to the theoretical monomeric value (37.6 kDa; Figure 2.14).

Two alternative hypotheses could account for this observed discrepancy in the molecular weight of TmTruB. The crystal structure (Figure 2.15) shows that the shape of TmTruB is distinctly rod-like rather than spherical, [47] which should lead to greater penetration into the pores of the size exclusion resin and therefore an anomalously low apparent molecular weight. In this scenario, the apparent molecular weight of TmTruB is distinctly underestimated in both buffers, and TmTruB is a monomer in Tris•HCl buffer but a dimer in phosphate buffer, which could be mimicking the phosphodiester backbone of RNA substrate. TruA, a member of a different family of Ψ synthases, appears to be a dimer in the crystal structure and behaves so in gel filtration in phosphate buffer.[77] In that case, the interaction between the dimers was such to make the oligomer more nearly spherical, but the putative TmTruB dimer would have to be an association of monomers that maintains an elongated shape to explain the data. This hypothesis seems less likely than the following one. The decrease in the apparent molecular weight of TmTruB in Tris *versus* phosphate buffer arises from a conformational

change, likely because the phosphate buffer mimics the phosphodiester backbone of RNA.

The crystal structures of TmTruB with and without [F^{5U}]RNA bound (Figure 2.22) show movement of a small domain (indicated by the arrow). In the apo form, the domain is tucked down next to the body of TmTruB but is flipped up and away from the body of TmTruB to interact with RNA. If phosphate induces an approximation of the latter conformation, it would decrease the penetration of TmTruB into the pores of the size exclusion resin and increase the apparent molecular weight (to that expected for a globular protein in order to explain the data). If the change in the apparent M_r of TmTruB in Tris buffer arises from a conformational change and the protein is truly monomeric, a population of TmTruB dimer (or higher oligomer) unable to react with [F^{5U}]RNA can account neither for the unbound TmTruB observed in SDS-PAGE gels nor the lack of correlation between the stoichiometry of product and adduct formation.

Implications for the turnover of [F^{5U}]TmTSL by TmTruB

The urea-PAGE analysis of the time course for the formation of [F^{5U}]TmTSL shows a slow but continually increasing ratio of adduct to free components over 3 h (Table 2.3). Also, the HPLC analysis of the time course performed in parallel to the gel analysis revealed that TmTruB achieves multiple turnovers of [F^{5U}]RNA just like EcTruB does. Similar to the urea-PAGE analysis, activity assays show that TmTruB—unlike EcTruB—gets increasingly inhibited upon exposure to [F^{5U}]RNA. While it is unlikely for a noncovalent adduct to survive

Figure 2.22: Crystal structures of TmTruB. A, Bound with RNA. B, Unbound. Comparison of the two structures shows a conformational change in a small domain (green, indicated by the arrows), which is tucked down in the unbound TruB but flipped away to interact with RNA in the bound form.

the denaturing conditions of gel electrophoresis, the seemingly contradictory results suggest that the adduct forms reversibly. The observation of the adduct on denaturing PAGE gels and the inhibition of TmTruB suggest that the adduct is covalent. The continuously changing ratio of adduct to free components on denaturing PAGE gels implies reversible adduction.

¹⁸O labeling studies

The ¹⁸O labeling studies with TmTruB show the incorporation of label into RNA rather than the conserved Asp. These results conclusively demonstrate that the additional oxygen atom in F⁵U* comes directly from solvent rather than from the conserved Asp through ester hydrolysis, as found previously with EcTruB, RluA, and TruA. [25, 42, 66] Such results strongly disfavor ester hydrolysis as the cause of hydration of F⁵U even in case of TmTruB. Unlike the case with the Ψ synthases examined earlier, the ¹⁸O content of F⁵U* reflects the isotopic composition of the last water in which TmTruB encountered the RNA. This unique result can arise from the following scenario. TmTruB releases unhydrated but rearranged F⁵U whether it initially binds [F⁵U]TmTSL or [F⁵U*]TmTSL, and the released species spontaneously hydrates in solution. In other words, TmTruB can both rearrange F⁵U and dehydrate F⁵U*. This continuous dehydration/rehydration of F⁵U* nicely explains the apparent discrepancy in the percentage of ¹⁸O content incorporated into F⁵U*. The binding equilibrium between TmTruB and [F⁵U]TmTSL or [F⁵U*]TmTSL is poised such that substantial amounts of free and bound enzyme are observed in denaturing gels. The existence of such a binding equilibrium is supported by the changing ratios of adduct to free TmTruB seen by urea-PAGE

with time (Figure 2.15) and in replicates (Figure 2.10), which indicates an exquisite sensitivity to fine variations in the reaction and gel conditions. Bound enzyme is inhibited in activity towards TmTSL^U (Figure 2.10), but free enzyme is sufficiently abundant to achieve multiple turnovers of [F⁵U]TmTSL as seen in the HPLC analysis for the formation of [F⁵U*]TmTSL (Figure 2.17). This makes the behavior of TmTruB intermediate between that of EcTruB (no observed adduct; multiple turnovers) and RluA and TruA (stoichiometric adduction; single turnover).

Helm and co-workers [78] recently hypothesized that the TmTruB-[F⁵U]RNA adduct is noncovalent based on spectroscopic studies using RNA decorated with fluorophores at different sites. [78] Those investigators did not observe an adduct between TmTruB and [F⁵U]RNA on urea-PAGE, which led them to conclude that the adduct is not stable enough to be covalent. [78] However, adduction is clearly shown here by both urea- and SDS-PAGE, although the levels were variable and the maximal level of adduct varied with the gel denaturant. Furthermore, Helm and co-workers used a lower percentage gel (10% *versus* 15%) and full-length tRNA transcript rather than stem-loop, which may contribute to the apparent discrepancy. The ability of the TmTruB-[F⁵U]TmTSL adduct to withstand the denaturing gel conditions supports the covalency of the adduct, even though a covalent bond was not visualized in the crystal structure of TmTruB with [F⁵U]RNA. [47] When Helm and co-workers observed a fast-forming band on SDS-PAGE gels, they reasonably concluded that such rapid formation of a covalent complex is precluded for an enzyme as slow as TruB. [78] Their conclusion was based on the kinetics of EcTruB, but TmTruB is a more efficient catalyst than its mesophilic

homolog (Table 2.7), so rapid formation of the TmTruB-[F⁵U]TmTSL adduct is not surprising. Also, Helm and co-workers initially assumed that TmTruB suicidally forms a covalent intermediate, but the collective results reported here imply that TmTruB and [F⁵U]RNA form a covalent adduct but do so *reversibly*.

The (still) consistent scheme for handling of F⁵U

Recently, Stroud and co-workers reported a cocrystal structure for RluB and [F⁵U]RNA in which a covalent adduct was found between the hydroxyl group of Tyr-146 and the pyrimidine ring of F⁵U (Chapter 1, [46]). Their results led them to the conclusions similar to the consistent scheme proposed by the Mueller group for the handling of F⁵U by Ψ synthases (Figure 2.23). The data reported here for TmTruB nicely fits the scheme. By any mechanism, TmTruB rearranges F⁵U to the C-glycoside. By virtue of the electrophilic C6, the rearranged F⁵U either gets trapped by an active site nucleophile (Tyr-146 in RluB; putatively the conserved Asp in RluA, TruA, and TmTruB), or gets released into solution and undergoes spontaneous hydration. After releasing [F⁵U*]TmTSL, TmTruB either binds [F⁵U]TmTSL or rebinds [F⁵U*]TmTSL for dehydration/rehydration. All data is consistent with the entrapment of the rearranged F⁵U.

Figure 2.23: The slightly revised scheme of Mueller and co-workers that still accounts for all the observed results.

CHAPTER 3

DEUTERIUM WASH-IN STUDIES TO PROBE THE GLYCAL MECHANISM

Pseudouridine synthases (Ψ synthases) rearrange 5-fluorouridine in RNA to its C-glycoside isomer just as they rearrange uridine to pseudouridine (Ψ). The behavior of different Ψ synthases differ towards $[F^5U]RNA$. TruA and RluA get irreversibly inhibited in handling $[F^5U]RNA$ and form an adduct that appears covalent by denaturing PAGE analysis. [29, 30, 36] *E. coli* TruB (EcTruB), on the other hand, is not inhibited by $[F^5U]TSL^4$ but instead converts F^5U into two rearranged, hydrated products (hereafter, the major and minor products).[25] *T. maritima* TruB (TmTruB) shows an intermediate behavior. TmTruB is only partially adducted at any given time, and enough free enzyme remains to perform multiple turnovers to generate the same major and minor products delivered by the action of EcTruB (Chapter 2).

⁴ *E. coli* TruB was previously shown to handle T-arm stem loop tRNA^{Phe} (TSL) as an excellent substrate with comparable kinetics to those for the full length tRNA^{Phe} substrate. [29]

Initially, two different mechanisms were proposed for the Ψ synthases. In the Michael mechanism, the conserved Asp attacks C6 of the pyrimidine ring of F⁵U to form a covalent Michael adduct (Figure 1.4), and rearrangement to the C-glycoside isomer and deprotonation of C5 complete the reaction. [36] In the acylal mechanism, the conserved Asp instead attacks C1' of the ribose ring to form an acylal intermediate (Figure 1.6); the detached uracilate anion then undergoes a net 180° rotation to reposition itself for C-glycoside formation to generate Ψ . [36]

Miracco and Mueller showed that the major product was the rearranged, hydrated species seen in the cocrystal structure of TruB with [F⁵U]RNA (Figure 3.1), [40] but the minor product was an *arabino* isomer of the major product, differing from it in the configuration at C2' of the pentose ring (Figure 3.1). [43] The minor product therefore requires epimerization at C2', so the mechanism must proceed through a glycal intermediate that is reprotonated on the opposite face to yield the observed *arabino* product. [43] With [F⁵U]RNA, the observed *arabino* product can be explained as part of the acylal mechanism. The increased acidity of 5-fluorouracil translates into reduced nucleophilicity for its anion relative to the uracilate anion, so the lifetime is lengthened for both the acylal intermediate and the oxocarbenium ion with which it is in equilibrium. [43] The increased acidity of C2' in the latter species makes it easier for the free—and therefore available—conserved Asp to deprotonate C2' from the “top” to form a glycal intermediate (Figure 3.2). Reprotonation from the “bottom” yields the *arabino* product of F⁵U.

The cocrystal structures of several Ψ synthases with [F⁵U]RNA reveal the conserved Asp to be the only acid/base group positioned in the vicinity of C2' and

major product: *ribo*

minor product: *arabino*

Figure 3.1: The identity of the major and minor products of F⁵U differ at the stereo configuration of C2'. [43]

Figure 3.2: The acylal mechanism recast to emphasize features that can account for the *arabino* product of F⁵U. The boxed manifold exists only for F⁵U because of the increased life time of the oxocarbenium ion that is in equilibrium with the acylal intermediate. [43]

so able to deliver a proton to the “bottom” face. Because the Michael mechanism has the conserved Asp tied up in an ester bond at this point, it cannot ferry a proton to the “bottom” face of the glycal to effect reprotonation. Therefore, the *arabino* product of F⁵U strongly disfavors the Michael mechanism.

If a glycal intermediate forms during the conversion of U to Ψ as it does during the reaction of F⁵U, an alternative mechanism arises: the ‘glycal’ mechanism (Figure 3.3), which can readily account for both the major and minor products of F⁵U (Figure 3.4). Uridine phosphorylase offers an enzymatic precedent for a glycal intermediate in the reaction of nucleotides. [44]. The deprotonation of C2’ to form the glycal intermediate can be achieved by either the conserved Asp or the O² on the pyrimidine ring. [44] Following the C-glycoside rearrangement, reprotonation of the pentose ring at C2’ generates Ψ (Figure 3.3).

Deuterium wash-in

If the reaction of [F⁵U]RNA with Ψ synthases proceeds through a glycal intermediate with the conserved Asp acting as a base to deprotonate C2’, the removed proton resides temporarily on the Asp, where it may be prone to exchange with the solvent protons (Figure 3.5) [79, 80]. If this is true, an observed deuterium “wash-in” would provide evidence for a glycal intermediate along the reaction pathway.

When TruB and RluA were incubated with U- and F⁵U-containing RNA, the mass spectra for the reactions run in unlabeled (H₂O) and labeled buffer (D₂O) were identical, indicating a lack of deuterium wash-in (Figure 3.6). [81] However,

Figure 3.3: The proposed 'glycal mechanism' for Ψ formation. The conserved Asp initiates the reaction by deprotonating C2' that leads to a glycal intermediate. After the C-glycoside rearrangement, C2' is re-protonated by the conserved Asp.

Figure 3.4: The 'glycol' mechanism with $[F^5U]RNA$. Reprotonation from the bottom face of the C2' would result in the observed *arabino* product of F^5U .

Figure 3.5: Deuterium wash-in scheme for the glycol mechanism with F^5U . If the proton on the conserved Asp can exchange with solvent on the time scale of the conversion of F^5U to its products, deuterium wash-in should be observed in both products of F^5U .

Figure 3.6: Mass spectra for the deuterium wash-in studies on RluA with RNAs containing U (*left*) and F⁵U (*right*). [10] In neither case was deuterium wash-in observed.

the lack of wash-in remains consistent with a glycal intermediate because the conserved Asp may be occluded from the solvent on the timescale of the conversion of U to Ψ or F^5U to F^5U^* . A careful literature review revealed that Y76L TruB offers an opportunity to probe this matter further.

Y76L TruB

The Ψ synthases show a conserved aromatic amino acid residue, which is a tyrosine in five of the six families and a phenylalanine in the TruD family. Phannachet *et al* mutated this tyrosine residue in *E. coli* TruB. The Y76F, Y76L, and Y76A variants lost the natural activity towards U, but Y76F and Y76L TruB still handle F^5U . [51] Although Y76F TruB generates both the major and minor products of F^5U , the Y76L TruB interestingly produces only the major product and does so slowly (Figure 3.7).[51] Phannachet *et al.* did not pursue this unusual behavior further, but it makes Y76L TruB ripe for deuterium wash-in studies for two reasons. First, if the lack of deuterium wash-in observed with wild-type TruB and RluA was due to the exclusion of solvent from the active site, the alteration in the geometry of the active site caused by the Y76L mutation might provide a path for solvent molecules to enter the active site, thereby resulting in deuterium wash-in. Second, the slower catalysis supported by Y76L TruB with $[F^5U]TSL$ will provide more time for the solvent to access the active site, perhaps enough to allow exchange of the proton that temporarily resides on the conserved Asp.

Figure 3.7: HPLC analysis of reaction products of 5FU-RNA incubated with *E. coli* Ψ 55S wild-type or Y76 mutants by Phannachet *et al.* [11] Each stem-loop RNA was incubated with the indicated TruB variants, and the product RNA was enzymatically digested to nucleosides and analyzed by reverse phase HPLC. * indicates impurity peaks. From reference 51.

Experimental section

General

Modified chymotrypsin (sequencing grade) was purchased from Roche (Indianapolis, IN). Immobilized pepsin was purchased from Fisher Scientific (Waltham, MA). RNA oligonucleotides were obtained from GE Dharmacon (Lafayette, CO), deprotected according to the manufacturer's protocol, and purified as described in Chapter 2. Deuterium oxide (99.9%) was obtained from Cambridge Isotope Laboratories, Inc. (Tewksbury, MA). Y76L TruB was generated *in silico* and energy-minimized using the GROMOS 43B1 force field [82] as implemented in Swiss-Pdb Viewer v4.0. [83] PyMOL v1.3 was used to generate high-resolution graphics of these structures. [84]

Subcloning, overexpression, and purification of Y76L TruB

The plasmid encoding Y76L TruB (pUL323) was created by introducing a point mutation into *truB* (from *E. coli*) in pΨ55 using the Stratagene QuickChange™ site-directed mutagenesis kit using the manufacturer's protocols with the following primers: 5'-GACTCCGACAAAGGTCTCCGGGTCATTGCG-3' (forward), and 5'-CTGTCCAAGACGCGCAATGACCCGG-3' (reverse); the sequence of the insert in pUL323 was verified by DNA sequencing. BLR(DE3) pLysS cells were transformed with pUL323 for the overexpression of Y76L TruB. Overexpressed Y76L TruB was purified over Ni-NTA resin (Qiagen) using the same protocol used for wild-type TruB. [64] Subsequently, Y76L TruB was polished over a POROS HQ anion exchange column (PE Biosystems) attached to a BioCAD SPRINT FPLC run by Perfusion Chromatography Workstation v3.01. Elution was achieved by

application of a gradient of potassium chloride (0.1–1.4 M) in 50 mM Tris•HCl buffer, pH 7.9; the enzyme generally eluted at 325–450 mM salt. Fractions bearing Y76L TruB were tested for RNase contamination, and the RNase-free fractions were pooled, concentrated, and stored at -20 °C in 50 mM HEPES buffer, pH 7.5, containing ammonium chloride (100 mM), EDTA (1 mM), and glycerol (10%,v/v).

Digestion and MALDI-MS analysis of Y76L TruB

Pepsin digestion

Y76L TruB (50–100 µg) was incubated for 5 min at 94 °C to denature the protein, which was pelleted by centrifugation (18,000g, 5 min). A slurry (120 µL) of immobilized pepsin in aqueous trifluoroacetic acid (0.1%, v/v), pH 2.5, was then added to the pelleted protein. After incubation for 12 h at 37 °C, an aliquot (10 µl) of the digest was loaded on to a ZipTip_{C18} pipetter tip (Millipore, Bedford, MA); the bound peptides were washed (10 × 10 µl) with aqueous trifluoroacetic acid (TFA) (0.1%, v/v) and eluted with matrix solution (5 µl), which was 4-chloro- α -cyanocinnamic acid (6.24 mg/ml) in 70% aqueous acetonitrile containing TFA (0.1%, v/v). The ZipTip eluate (1 µl) was spotted on a MALDI sample plate and air dried. Mass spectra were acquired using a Voyager DE-Pro MALDI-TOF instrument (PE Biosystems, Foster City, CA) with acquisition in positive reflectron mode with an extraction delay time of 200 ns and 400 laser shots per spectrum. Calibration was achieved using a 1:1:2 mixture of Bradykinin fragment 1-7 (757.399 monoisotopic mass), fragment 18-39 of ACTH (2465.1989), and the oxidized β -chain of insulin (3494.6513).

Chymotrypsin digestion

Y76L TruB (50 µg) was heat-denatured and pelleted as described above. The pellet was suspended in 100 mM Tris buffer, pH 7.8, containing calcium chloride (10 mM), to which chymotrypsin (2 µg) was added followed by incubation for 12 h at 37 °C. An aliquot (10 µL) of the digestion mixture was desalted using ZipTip_{C18}, and mass spectra were acquired as described above for the pepsin digestion.

Analysis of Y76L TruB and [F⁵U]TSL reaction

Y76L TruB (10 µM) was incubated at 37 °C with [F⁵U]TSL (50 µM) in 50 mM HEPES buffer, pH 7.5, containing ammonium chloride (100 mM), EDTA (1 mM), and DTT (5 mM) (hereafter, standard reaction buffer). Aliquots (30 µL) were withdrawn at 3 h and 6 h and quenched by mixing with 2x Laemmli buffer (30 µL). Following this, the sample was either heated for 5 min at 94 °C or loaded directly onto the gel (0.1% v/v, 10%, 10×10 cm), which was run (165 V, 80-90 min) and stained with CoomassieTM Blue to visualize protein bands.

For HPLC analysis of the RNA, an aliquot (10 µL) of the reaction mixture was diluted into S1 nuclease digestion buffer (90 µL), which is 30 mM sodium acetate buffer, pH 4.6, containing sodium chloride (50 mM), zinc chloride (10 mM), and glycerol (5%, v/v). S1 nuclease (0.5 µL, 50 U) was added, and the mixture was incubated for 1 h at 37 °C and then at 94 °C for 5 min followed by cooling on ice for 5 min. Subsequently, a fresh aliquot of S1 nuclease (1 µL, 100 U) and alkaline phosphatase (3 µL, 3 U) were added, and the mixture was incubated for 3 h at

37 °C. The digestion mixture was then analyzed over an SB-C₁₈ analytical column connected to Beckman Coulter System Gold HPLC (Indianapolis, IN) equipped with a Model 168 programmable diode array detector module.

Inhibition of Y76L TruB by [F⁵U*]TSL

Y76L TruB (10 µM) was either pre-incubated with [F⁵U*]TSL (20 µM) for 15 min at 37 °C or was allowed to react directly with [F⁵U]TSL (50 µM) in standard reaction buffer (60 µL) at 37 °C. Aliquots (10 µL) of the reaction mixture were withdrawn at various times (0-240 min) and were immediately quenched by incubation in boiling water for 5 min followed by cooling on ice for 5 min. The aliquot was then diluted into S1 nuclease digestion buffer (90 µL), digested with S1 nuclease, dephosphorylated with alkaline phosphatase, and analyzed by reverse phase HPLC as described above.

Deuterium wash-in

Deuterated standard reaction buffer was prepared by repeated lyophilization (3x) of the standard reaction buffer to dryness and redissolution in D₂O (>99%). All exchangeable protons in [F⁵U]TSL were replaced with deuterium by three cycles of dissolution and lyophilization with deuterated buffer. [F⁵U]TSL (50 µM) in deuterated standard reaction buffer (146.5 µL) was incubated for 5 min at 37 °C before the reaction was started by the addition of Y76L TruB (10 µM, 3.5 µl), which resulted in a final deuterium content of 96.6%. After 4 h at 37 °C, the reaction was heated to 94 °C for 5 min, cooled on ice for 5 min, centrifuged (18,000g, 5 min) and spun to pellet the protein, which was discarded. Residual

protein was extracted from the supernatant with 1:1 phenol:chloroform, and the RNA was precipitated with ethanol and air-dried. The RNA was redissolved in S1 nuclease digestion buffer (100 μ L), and digested to nucleosides by the combination of S1 nuclease (2 $\times$ 5 μ L with heat denaturation in between, 500 U) and alkaline phosphatase (5 μ L, 5 U). After the complete digestion was confirmed by analytical HPLC, F⁵U* was isolated by preparative reverse phase HPLC over an ultrasphere•C₁₈ column (5 μ M, 10 $\times$ 250 mm; Beckman-Coulter, Fullerton, CA), eluting with a gradient of acetonitrile in water using the method described elsewhere [85] but with a flow rate of 3 mL/min; under these conditions, F⁵U* eluted at 4-4.5 min. The fractions containing F⁵U* were combined and concentrated to dryness *in vacuo*, and a part of the residue was dissolved in water (15 μ L) and then diluted with a 1:1 (v/v) mixture of methanol and formic acid (135 μ L). The F⁵U* was then analyzed by high resolution mass spectrometry in negative mode on a Thermo Finnigan (Bremen, Germany) Linear trap quadrupole Eourier transform (LTQ-FT) mass spectrometer equipped with a Triversa Nanomate (Ithaca, NY) direct infusion nano – electrospray ion (nESI) source. An unlabeled control reaction was run by incubating TruB (10 μ M) with [F⁵U]TSL (50 μ M) in standard reaction buffer (150 μ L) followed by analysis as described above. Data was analyzed using Xcalibur™ v. 2.0 (Thermo Electron; Waltham, MA). For the labeled reaction (96.66%, D₂O, the isotopic contributions from each element (²H, ¹³C, ¹⁵N, ¹⁸O *etc.*) in M+1 and M+2 peaks were calculated relative to the intensity of the monoisotopic peak, which was set to a value of 100%. The difference between the relative intensity value thus obtained for ²H and the relative intensity of the monoisotopic

peak from the unlabeled reaction was then adjusted by the isotopic composition of the labeled buffer (96.66%, D₂O) to obtain the percentage of deuterium wash-in. Spectral simulations for a set percentage of deuterium incorporation were obtained using the embedded 'isotope simulation' tool in Xcalibur™ v. 2.0. This was achieved by manually defining the mole fractions of protium and deuterium in the chemical formula for the dinucleotide product of F⁵U.

Results

In silico analysis

An overlap of the cocrystal structure of wild-type TruB and [F⁵U]RNA [40] with that of *in silico* Y76L TruB [83, 84] showed a comparatively spacious active site for the variant, primarily due to the lack of steric hindrance associated with the phenyl ring of Tyr-76 (Figure 3.8 and 3.9). The energy-minimized structure for Y76L TruB shows the side chain of Leu-76 positioned perpendicular to the pyrimidine ring of F⁵U, in contrast to the more nearly parallel orientation of the Tyr-76 phenyl ring in wild-type TruB (Figure 3.8). The effect of the Y76L mutation on the positioning of F⁵U in the active site could not be fully determined because of software limitations that allow energy minimization for the enzyme itself but not bound molecules, including the RNA substrate. [12, 13] The space-filling views of the active sites for Y76L and wild-type TruB (Figure 3.9) were compared to see if the conserved Asp may now have access to exchange freely with bulk solvent. Even though the RNA remained rigidly fixed, the active site definitely appears more accessible to solvent.

Subcloning, overexpression and purification of Y76L TruB

To introduce the Y76L point mutation to N-terminally His₆-tagged TruB, pUL323 was created from its parent plasmid pΨ55. Overexpressed Y76L TruB was purified to near homogeneity by nickel affinity chromatography followed by anion exchange chromatography. Subsequent storage of Y76L TruB under conditions similar to those used for wild-type TruB [64] resulted in >50% loss of

Figure 3.8: An *in silico* comparison of the active sites of TruB variants. A, Y76L TruB. B, wild-type TruB. The energy-minimized structure for Y76L TruB shows different positioning of Leu-76 and Tyr-76 with respect to F⁵U. [51]

Figure 3.9: Space-filling view of the active site of TruB variants. A, Y76L TruB. B, Y76L TruB. Active site amino acids other than the conserved Asp-48 and Tyr/Leu-76 are in green. The lower view is rotated 180° relative to the upper view. Extra space is introduced around the pyrimidine ring of F⁵U as a result of the mutation.

activity within one week. This instability was successfully addressed by storage at $-20\text{ }^{\circ}\text{C}$ in 50 mM HEPES buffer, pH 7.5, containing ammonium chloride (100 mM), EDTA (1 mM), and glycerol (10%, v/v). Under these conditions, the stability of Y76L TruB improved, with <15% loss of activity after one month.

MALDI-MS of Y76L TruB

The sequence of Y76L TruB was verified by MALDI-TOF MS analysis after digestion with chymotrypsin (Figure 3.11) or pepsin (data not shown). When compared to the digest of wild-type TruB, the expected shift of 50 m/z was observed for the variant peptide containing Leu in place of Tyr-76.

Reaction of Y76L TruB with [F⁵U]TSL

Identity of the F⁵U product of the Y76L

Y76L TruB (10 μM) was incubated with [F⁵U]TSL (10 μM) in standard reaction buffer for 3 h at 37 $^{\circ}\text{C}$. The RNA sample from this reaction was digested to individual nucleosides and analyzed by reverse phase HPLC. A peak was observed with identical retention time to the major (*ribo*) product of F⁵U from the action of wild-type TruB (Figure 3.12). A co-injection of the S1 nuclease-digested RNA resulting from the action of wild-type and Y76L TruB on [F⁵U]TSL confirmed this assignment (Figure 3.12).

Figure 3.11: Partial mass spectra of the peptides from the chymotryptic digestion of Y76L (*lower*) and wild-type TruB (*upper*). A change in mass is observed for the peptide $^{69}\text{LLDSDKR}\text{X}^{76}$ from wild-type TruB (X = Tyr, 1009.52 m/z_{pred}) versus Y76L TruB (X = Leu, 959.54 m/z_{pred} ; results from non-canonical cleavage after Leu by chymotrypsin).

Figure 3.12: Partial HPLC trace of the products of F⁵U from the action of wild-type (blue) and Y76L (green) TruB. Co-injection results in a stoichiometric increase in the integration for the major product of F⁵U. *, buffer peaks.

SDS-PAGE analysis

To test whether the variant enzyme can form an adduct with [F⁵U]RNA, Y76L TruB (10 µM) was incubated with [F⁵U]TSL (50 µM) in standard reaction buffer for 3-6 h at 37 °C. Aliquots of this reaction were analyzed by SDS-PAGE. Similar to the behavior of wild-type TruB, [25] no adduct was observed with Y76L TruB even after 6 h of incubation with [F⁵U]TSL (Figure 3.13).

Time course for the formation of [F⁵U*]TSL

To see whether Y76L TruB can achieve multiple turnovers of [F⁵U]TSL like wild-type TruB, [F⁵U]TSL (50 µM) was incubated with Y76L TruB (5-10 µM) in standard reaction buffer for 12 h at 37 °C. Aliquots (10 µL) of this reaction were withdrawn at regular time intervals, and the RNA was digested to individual nucleosides and analyzed by HPLC. Wild-type TruB (200 nM) completely turns over [F⁵U]TSL (20 µM) within 3 h, [25] but Y76L TruB achieved only ~2.5 turnovers even after 12 h (Table 3.1). Also, the enzyme slowed considerably after the first turnover; it is ~600-fold slower than the wild-type TruB. The observed decrease in the activity of Y76L TruB towards [F⁵U]TSL raises the question of whether the rate of the reaction is being limited by slow product dissociation. To address this issue, Y76L TruB (10 µM) was incubated with [F⁵U*]TSL (20 µM) in standard reaction buffer for 15 min at 37 °C before the addition of [F⁵U]TSL (50 µM). The pre-incubation led to a ~16-fold decrease in the rate of formation of [F⁵U*]TSL (Figure 3.14, Table 3.2).

[F ⁵ U]TSL (μM)	50	50	50	50	0	0

The plotted values for the reaction with pre-incubation (□) are adjusted by subtraction of the [F⁵U*]TSL (20 μM) originally present.

Deuterium wash-in

Y76L TruB (10 μ M) was incubated with [F⁵U]TSL (40 μ M) in either unlabeled or deuterated standard reaction buffer for 4 h at 37 °C. A comparison of the product of F⁵U (F⁵U*pC)⁵ from the reaction run in labeled *versus* unlabeled buffer revealed that a low amount of deuterium wash-in occurred (Figure 3.15 and Table 3.3). The isotopic contribution from ²H can be clearly seen for the M+1 and M+2 peaks (Figure 3.16) with the contributions from ²H and ¹³C clearly resolved (insets). Based on these high-resolution spectra, 4.45% wash-in was calculated. Repetition of the wash-in experiments, however, showed a lower percentage (0.52% and 0.92%) of deuterium incorporation into F⁵U*pC (Table 3.4).

⁵ The product of F⁵U was isolated as a dinucleotide with cytidine on the 3'-end (F⁵U*pC). This was because of the inability of S1 nuclease to cleave after non-planar bases such as F⁵U*.

Figure 3.15: Comparative FT-MS of the purified dinucleotide F^5U^*pC . A, Natural abundance isotopic distribution. B, Observed isotopic distribution for the reaction in unlabeled buffer. C, Observed isotopic distribution for the reaction in labeled buffer (96.66% D_2O).

Figure 3.16: High resolution mass spectrum of $[F^5U^*pC]^-$. The inserts show close-up views of the $M+1$ and $M+2$ ion clusters. The spectra for the dinucleotide obtained from the reaction run in unlabeled buffer (H_2O) and deuterated buffer (D_2O) are presented along with simulated spectra for natural abundance and for 5% non-exchangeable deuterium (5%D). A deuterium incorporation of 4.45% from the solvent was observed. *, unidentified peaks absent in the control mass spectrum of solvent.

Discussion

In silico analysis showed that the Y76L substitution results in a more open TruB active site that may provide greater access to solvent molecules and thus allow deuterium wash-in. A plasmid encoding Y76L TruB was generated and used to overexpress the variant enzyme. Purified Y76L TruB was stored under slightly modified conditions since activity was lost under the storage conditions used for wild-type TruB. [86]

The initial characterization of Y76L TruB by Phannachet *et al.* did not include denaturing PAGE analysis to test if this variant forms an adduct when incubated with [F⁵U]TSL. As with wild-type TruB, no adduct was observed for Y76L TruB on SDS-PAGE gels, even after prolonged incubation with [F⁵U]TSL (Figure 3.14). Also, reverse phase HPLC analysis of product nucleotides showed that Y76L TruB handles [F⁵U]TSL and forms a rearranged, hydrated product from F⁵U. However, in contrast to wild-type TruB, Y76L TruB forms a single product, which was confirmed as the major (*ribo*) product generated by the action of wild-type TruB (Figure 3.1). One explanation for the formation of a single product of F⁵U could be that the Tyr to Leu substitution induces a change in active site geometry that alters the relative positions of the F⁵U and conserved Asp. In this scenario, the conserved Asp may no longer be able to access the ribose ring from the “bottom” face to yield the *arabino* product of F⁵U. However, this hypothesis cannot be confirmed because a cocrystal structure of Y76L TruB with [F⁵U]TSL has not been reported, and the limitations of the *in silico* analysis [83, 84] do not allow

confidence that it can deliver definitive changes in the positioning of the active site groups.

Y76L TruB catalyzes the reaction of F^5U ~600 fold slower than does wild-type TruB, and the first turnover occurs much faster (Table 3.1, Figure 3.14). This slow activity of Y76L TruB towards $[F^5U]TSL$ could be a case of product inhibition that is caused either by the slow dissociation of $[F^5U^*]TSL$ from the enzyme after the initial turnover or a binding competition between $[F^5U^*]TSL$ and $[F^5U]TSL$. To answer this question, Y76L TruB was pre-incubated with $[F^5U^*]TSL$ (1:2) in standard reaction buffer followed by assaying with $[F^5U]TSL$. HPLC analysis of this reaction showed a ~16 fold reduction in the initial rates of formation of $[F^5U^*]TSL$ (Figure 3.14, panel B), a result that indicates competition between the $[F^5U]TSL$ and its product.

Deuterium wash-in

High resolution mass spectrometry

A mass spectrum consists of a sum of signals from species of various possible isotopologues (for example, ^{13}C , ^{15}N , 2H , etc.). The isotopic distribution for each singly charged molecular species consists of peaks spaced 1 m/z apart. The monoisotopic peak, which is the isotopologue with only the most abundant isotope of each element, uniquely reflects elemental composition as every other peak in the mass spectrum represents contributions from different combinations of less abundant isotopes of the constituent elements. For example, a species of the monoisotopic mass +2 m/z ($M+2$) can represent an isotopic combination of two

^{13}C , two ^{15}N , one ^{13}C and one ^{15}N , two ^2H , *etc.* Such elemental combinations, however, differ from each other by a few mDa, and a mass spectrometer of sufficiently high resolution can distinguish the contribution from each element. In the current study, the contribution from ^2H is at issue.

Deuterium incorporation into the $[\text{F}^5\text{U}^*]\text{TSL}$

Deuterium wash-in was anticipated because the *in silico* analysis—despite its limitations—clearly indicated a more open active site in Y76L TruB. The observed 4.45 % deuterium incorporation bore out this prediction (Figure 3.16; Table 3.3). Replicates were run to confirm the low level of wash-in, and they showed even lower levels (0.52% and 0.92%) of deuterium incorporation into the product of F^5U . The significance of these minute levels of wash-in must be viewed with skepticism. Although substantial wash-in would have been informative, its absence is not because the removed proton may remain occluded from the solvent even in the Y76L variant. A more definitive approach to test the glycal mechanism is to seek for a primary kinetic isotope effect by comparing the reaction rates of substrates prepared with $[2'\text{-}^2\text{H}]\text{U}$ with those of unlabeled substrates, which is presented in Chapter 4.

CHAPTER 4

DEUTERIUM KINETIC ISOTOPE EFFECT STUDIES TO PROBE THE GLYCAL MECHANISM

Pseudouridine synthases (Ψ synthases) convert uridine (U) to its C-glycoside isomer pseudouridine (Ψ). They are classified into six different families that share no statistically significant global sequence similarity but have identical folds and are thus thought to have resulted from divergent evolution. [18] An active site aspartic acid residue conserved among all Ψ synthases (hereafter, the 'conserved Asp') is absolutely essential for the activity. [64] Ψ synthases TruA and RluA get irreversibly inhibited by 5-fluorouridine-containing RNA ($[F^5U]RNA$), [29, 30, 36] which led to the proposal of the 'Michael mechanism', in which the conserved Asp forms a Michael adduct with C6 of the pyrimidine ring (Figure 4.1) [36]. The alternative 'acylal mechanism' involves the conserved Asp as a nucleophile, but with attack at C1' of the ribose ring to form an acylal intermediate (Figure 4.2) [36]

Ψ synthases differ in their action towards $[F^5U]RNA$. While TruA and RluA get irreversibly inhibited and form an adduct that appears covalent by denaturing

Figure 4.1: The ‘Michael mechanism’ for Ψ synthases. The conserved Asp makes a nucleophilic attack at C6 to form a Michael adduct. *N*-glycosidic bond cleavage followed by a net 180° rotation of the adducted pyrimidine repositions it for the subsequent C-glycoside formation. Expulsion of the conserved Asp followed by the deprotonation of C5 generates Ψ.

Figure 4.2: The ‘acylal mechanism’ for Ψ formation. This mechanism begins with the conserved Asp making a nucleophilic attack at C1' of the ribose ring, either through a concerted or step-wise process, thereby displacing the pyrimidine ring. The uracilate anion rotates to reposition itself to effect C-glycoside formation. The expelled Asp deprotonates C5 to generate Ψ .

PAGE analysis, [30, 36] *E. coli* TruB does not get inhibited and turns over [F⁵U]TSL⁶ into two rearranged and hydrated products (hereafter, the ‘major’ and ‘minor’ products of F⁵U). [25] NMR experiments by Miracco and Mueller showed that TruB and RluA form the same products of F⁵U which differ in the sugar rather than the pyrimidine ring: the major product of F⁵U was the *ribo* isomer previously found in the cocrystal structure of TruB and [F⁵U]RNA [40] whereas the minor product was the *arabino* isomer (Figure 3.1). [43]

The change in configuration at C2’ requires epimerization during formation of the minor *versus* the major product. C2’ must be deprotonated to form a glycal intermediate followed by reprotonation from the “bottom” face. (Figure 4.3) [43] The deprotonation of C2’ can be achieved either by the conserved Asp or O² of the pyrimidine ring. [87] However, the conserved Asp is the only acid/base group positioned near enough to C2’ to donate a proton to its “bottom” face—an observation that strongly argues against the Michael mechanism since the conserved Asp is tied up as an ester.

The *arabino* product of F⁵U is still consistent with the acylal mechanism (Figure 3.2). [43] The diminished nucleophilicity of the anion of 5-fluorouracil results in an increased lifetime for the acylal intermediate and the oxocarbenium species with which it is in equilibrium. [43] The increased acidity of C2’ in the oxocarbenium species makes its deprotonation by the detached conserved Asp

⁶ Ψ synthase TruB was previously shown to handle stem-loop substrate (TSL) as well as the full length tRNA substrate. [29] The same is true for RluA with ASL. [30]

easier, and reprotonation of C2' from the opposite face results in the *arabino* product of F⁵U (Figure 3.2).

A glycal intermediate along the Ψ synthase reaction with U opens up a new mechanistic possibility, the 'glycal mechanism' (Figure 4.3), which can easily explain both the major and minor products of F⁵U (Figure 4.4) and is preceded by uridine phosphorylase [87]. With normal substrate (containing U), the mechanism proceeds through the deprotonation of C2' either by the conserved Asp or by the O² of the pyrimidine ring to eliminate the anion of uracil and form the glycal intermediate. Following rotation of the detached pyrimidine ring and C-glycoside formation with reprotonation of C2', deprotonation of C5 by the conserved Asp generates Ψ .

If the conserved Asp deprotonates C2', the removed proton resides temporarily on the Asp, where it may be prone to exchange with the solvent protons and therefore provide strong evidence for a glycal intermediate (Figure 3.5). [79, 80] With TruB and RluA, deuterium wash-in studies conclusively ruled out such exchange with both U- and F⁵U-containing RNA substrates. Wash-in experiments with the carefully chosen Y76L TruB that has a more open active site resulted in a very low (<4.5%) deuterium incorporation into the products of F⁵U (Chapter 3). The lack of wash-in during the formation of minor product of F⁵U (25-33% of total products) clearly shows that the proton removed from C2' is rigorously occluded from bulk solvent on the time scale of reaction. The same scenario for the conversion of U to Ψ or F⁵U to the major product—neither of which *requires* deprotonation of C2'—leaves the lack of wash-in consistent with the glycal

Figure 4.3: The proposed 'glycal mechanism' for Ψ formation. The conserved Asp initiates the reaction by deprotonating C2' that leads to a glycal intermediate. After the C-glycoside rearrangement, C2' is reprotonated by the conserved Asp.

Figure 4.4: The glycol mechanism with $[F^5U]RNA$. Following the deprotonation of $C2'$ by the conserved Asp that leads to the glycol intermediate formation, reprotonation from the bottom face of the $C2'$ would result in the observed *arabino* product of F^5U .

mechanism. A more direct and definitive approach than wash-in was sought to obtain evidence for the glycal mechanism.

Deuterium kinetic isotope effect

If the Ψ synthase reaction proceeds through a glycal intermediate, deprotonation or reprotonation of C2' (or both) may be partially rate-limiting. In this case, substituting the proton on C2' of U and F⁵U with deuterium (Figure 4.5) should display a primary, deuterium kinetic isotope effect (²KIE), [88] manifested by a reduction in rate. To test this scenario, stem-loop substrates for TruB and RluA were prepared with [2'-²H]U, and their rates were compared with unlabeled substrates.

Figure 4.5: The glycol mechanism with [2'-²H]U containing substrate. If either deprotonation or reprotonation of C2' is partially rate limiting, a primary ²KIE will be observed.

Experimental

All standard chemicals, unless specified were purchased from Fisher Scientific (Pittsburgh, PA) or Sigma Aldrich (Milwaukee, WI). [2'-²H]ribose was purchased from Omicron Biochemicals, Inc. (South Bend, IN). Restriction endonucleases NdeI and BamHI and thermostable inorganic pyrophosphatase were purchased from New England BioLabs (Ipswich, MA). Phosphoenolpyruvate (PEP) was purchased from Chem-Impex International (Wood Dale, IL). Pyruvate kinase/lactate dehydrogenase enzyme cocktail, pyruvate kinase II from rabbit muscle, ribose 5-phosphate barium salt (R5P•Ba), Dowex-50 (H⁺ form), and Norit[®] and Darco G-60 activated charcoal were obtained from Sigma Aldrich (Milwaukee, WI). The Dowex-50 (H⁺ form) was cleaned by the method of Cleland. [89] Prior to use, the activated charcoal (2 g) was mixed with 0.01 N HCl (30 mL); the mixture was centrifuged (8000g, 15min), and the supernatant was discarded. Yeast myokinase was purchased from CalBiochem (Billerica, MA). Amicon DIAFLO ultrafiltration units were purchased from Millipore Corporation (Bedford, MA). Bond Elut C8 solid phase extraction cartridges (5 g, 20 mL) were obtained from Agilent (Santa Clara, CA). DNA oligonucleotides were purchased from Integrated DNA Technologies (Coralville, IA). Ribonucleotide triphosphates (rNTPs) were purchased from Promega (Madison, WI), and T7 RNA polymerase was purchased from Epicentre biotechnologies (Madison, WI). Stop RNase Inhibitor RX was purchased from 5 PRIME, Inc. (Gaithersburg, MD), and TURBO[™] DNase was purchased from Life Technologies (Carlsbad, CA). Phosphoribosyl pyrophosphate (PRPP) was freshly isolated by the method of Gross *et al.* [90] All coupled

enzymatic activity assays were performed with a DU[®] 800 Series UV/Vis spectrophotometer (Beckman Coulter; Pasadena, CA) equipped with a six cell transporter and a Peltier temperature controller. NMR spectra were acquired using a 400-MR spectrometer equipped with a 5 mm direct HX z-PFG broadband probe (Varian Inc., Palo Alto, CA)

Enzymatic synthesis of [2'-²H]UTP

Subcloning, overexpression and purification

Ribokinase. The plasmid (pET22-HT) bearing the ribokinase gene (*rbkS*) was generously provided by J. Williamson, [91, 92] but it did not properly express ribokinase. DNA sequencing revealed an overhang after the stop codon and an inverted duplication at the 5'-end. To rectify these errors, NdeI and BamHI restriction sites were introduced at the 5'- and 3'-ends of *rbkS*, respectively, by PCR amplification with the following primers: 5'-GCTCCTCATATGCAAAACGCAGGCAGCC-3' (forward), and 5'-GCTTCGGGATCCTCACCTCTGCCTGT-3' (reverse). The PCR product was digested with both NdeI and BamHI and ligated into pET-15b (Novagen; Billerica, MA) opened with the same restriction enzymes to create pUL600 for the expression of ribokinase with N-terminal His₆-tag. The proper insertion of *rbkS* into the plasmid was verified by DNA sequencing. BLR(DE3) pLysS was transformed with pUL600, and ribokinase was overexpressed and purified over Ni-NTA resin (QIAGEN) according to a published protocol. [64] Purified fractions of ribokinase were tested for activity, pooled, concentrated, and dialyzed overnight into the final

storage buffer, which is 50 mM phosphate buffer, pH 7.5, containing sodium chloride (150 mM) and glycerol (50%, v/v), for storage at -20 °C until needed.

PRPP synthetase and uracil phosphoribosyl transferase (UPRTase). The plasmids encoding *Salmonella typhimurium* PRPP synthetase and *E. coli* UPRTase were generously provided by S. Van Lanen. [93] Both plasmids were based on pET-30a (+) (Novagen) so that the encoded proteins are expressed with an N-terminal His₆-tag. Following transformation of BLR(DE3) pLysS cells with these plasmids, PRPP synthetase and UPRTase were overexpressed and purified over Ni-NTA resin. Column fractions were assayed for activity, and enzyme-bearing fractions were pooled, concentrated, and stored -20 °C in 50 mM sodium phosphate buffer, pH 7.5, containing sodium chloride (300 mM) and glycerol (50% v/v).

Ribokinase assay

The activity of ribokinase (Figure 4.6) was determined using an assay coupled to the consumption of NADH. [90, 92] The reaction mixture (1 mL), was 50 mM Tris•HCl buffer, pH 7.5, containing D-ribose (50 mM), potassium chloride (100 mM), magnesium chloride (10 mM), NADH (0.2 mM), ATP (3 mM), PEP (1 mM), pyruvate kinase (3.3 µL, 2 U), and lactate dehydrogenase (3.3 µL, 2 U). The cuvette containing the reaction mixture was inserted into the spectrophotometer and held at 25 °C until a steady base line was observed at 340 nm. Ribokinase (<1 µL, 1 µg) was then added, and the contents of the cuvette were mixed by inversion. The change in A₃₄₀ was monitored with time, and the rate of change and ϵ_{340} of NADH (6220 M⁻¹•cm⁻¹) was used to calculate ribokinase activity (Table 4.1).

R5P•Na

R5P•Ba (100 mM, 1mL) was exchanged into its sodium form (R5P•Na) by passing it through column (2 × 1 cm) of Dowex-50 (Na⁺ form). R5P•Na was quantitated by dephosphorylating it with alkaline phosphatase and measuring the concentration of the released inorganic phosphate by the Ames test. [94]

PRPP synthetase assay

The assay of PRPP activity (Figure 4.6) also rested on coupling to NADH consumption. [90, 95] The assay mixture (1 mL) was 100 mM sodium phosphate buffer, pH 7.6, containing R5P•Na (5 mM), magnesium chloride (7 mM), NADH (0.2 mM), ATP (3 mM), PEP (1 mM), pyruvate kinase (3.3 μ L, 2 U), myokinase (4 μ L, 4 U), and lactate dehydrogenase (3.3 μ L, 2 U). After a steady baseline was observed at 340 nm, PRPP synthetase (<1 μ L, 1 μ g) was added, and the contents of the cuvette were mixed by inversion. The change in A_{340} was monitored with time, and the rate of change and ϵ_{340} of NADH (6220 M⁻¹•cm⁻¹) was used to calculate the activity (Table 4.1)

UPRTase assay

The assay for UPRT activity (Figure 4.6) is based the change in $\Delta\epsilon_{271} = 2763 \text{ M}^{-1}\cdot\text{cm}^{-1}$ for uracil and UMP (greater ϵ_{271}). [91] The assay mixture (1 mL) was 50 mM Tris•HCl buffer, pH 7.5, containing magnesium chloride (5 mM), PRPP (1.5 mM), and uracil (0.1 mM). After a steady baseline was observed at 271 nm, UPRTase (<1 μ L, 1 μ g) was added and ΔA_{271} was monitored.

Figure 4.6: Schemes of the activity assays for the overexpressed enzymes. A, Ribokinase. B, PRPP synthetase. C, UPRTase. MK, myokinase; PK, pyruvate kinase; LDH, lactate dehydrogenase.

Synthesis of [2'-²H]uridine triphosphate

The published enzymatic synthesis of [2'-²H]UTP [91, 92] was adapted to a smaller scale (400 μ mol). In a 50 ml tube, 2'-[²H]D-Ribose (60.7 mg, 400 μ mol) and uracil (44.8 mg, 400 μ mol) were dissolved in synthesis buffer (50 mL), which is 50 mM potassium phosphate buffer, pH 7.5, containing DTT (20 mM), kanamycin (0.1 mM), ATP (0.5 mM), ampicillin (5 mM), magnesium chloride (10 mM), and PEP (40 mM). The synthesis was initiated by the addition of ribokinase (50 U), PRPP synthetase (50 U), UPRTase (2 U), nucleoside monophosphate kinase (2 U), myokinase (37.5 U), and pyruvate kinase (75 U). [96] The reaction was monitored both by ³¹P NMR and an assay of pyruvate formation. [91, 92] After 108 h, no further increase in the amount of 2'-[²H]UTP was detected by ³¹P NMR, and the reaction was judged to be essentially complete (>90%) by pyruvate production. The reaction mixture was filtered through an Amicon DIAFLO YM-10 membrane (10,000 MWCO) to remove enzymes, and activated charcoal (2 g) was added to the reaction mixture (~48 mL) to adsorb UMP. After nutation for 15 min at 4 °C, the charcoal was pelleted by centrifugation (8000g, 15 min). After ensuring that the bulk of [2'-²H]UTP (and ATP) was adsorbed to charcoal by measuring the absorbance of supernatant at A₂₆₀, the supernatant was discarded. The charcoal was washed successively with ice-cold water (20 mL) and aqueous ethanol (20 mL; 2.5%, v/v) containing ammonium hydroxide (0.5%, v/v). Finally, the charcoal-bound [2'-²H]UTP along with other “sticky” reaction components (primarily PEP and ATP) were eluted twice with aqueous ethanol (30 mL; 50% v/v) containing ammonium hydroxide (0.5% v/v). [97]. The ethanolic elutions (60 mL) containing

2'-[²H]UTP were combined and filtered through a Steriflip® vacuum filter unit to remove residual charcoal. The pH was adjusted to 6.5 using acetic acid (1 M), and the solution was evaporated to dryness *in vacuo*, which yielded [2'-²H]UTP as yellowish white powder (247 μmol, 69% yield).

To remove PEP and ATP that co-eluted with [2'-²H]UTP, the yellowish white powder was redissolved in 5 mM triethylammonium acetate buffer (1 mL), pH 7.0, and loaded onto a Bond Elut C8 SPE cartridge pre-equilibrated with the same buffer: elution was achieved with a step gradient of aqueous acetonitrile (0-50%, v/v in 10% steps). 2'-[²H]UTP eluted between 0-2.5% acetonitrile. The fractions containing 2'-[²H]UTP were detected by the characteristic absorbance of uridine at 260 nm. These fractions were combined, and reduced in volume *in vacuo* using a rotary evaporator. Triethylammonium acetate was removed by the repeated addition and removal of water and isopropanol *in vacuo* with maintenance of pH ~8.0 by the addition of aqueous sodium hydroxide (1 M). The [2'-²H]UTP was recovered as a white powder and stored at -80 °C (165 μmol, 46% yield).

¹H NMR (400 MHz; D₂O) δ: 7.95 (H⁶, 1H, doublet, *J* = 8.4 Hz), 5.95 (H^{1'}/H⁶, 2H, multiplet), 4.31 (H^{3'}, 1H, doublet, *J* = 5.0 Hz), 4.23 (H^{4'}/H^{5'}/H^{5''}, 3H, broad multiplet).

³¹P NMR (162 MHz; D₂O; 1H) δ: -5.97 Hz (α), -9.98 Hz (γ), -21.20 Hz (β).

***In vitro* transcription of RNA substrates**

Unlabeled TSL. The partially double-stranded DNA template was prepared using commercially obtained oligonucleotides that had the following sequence: 5'-ATTATGCTGAGTGATATCGACACAAGCTAGGTGTC-3' (where underlining

denotes the template sequence for TSL) and 5'-TAATACGACTCACTATAGC-3'. The template was annealed by incubating the strands together (50 mM each in a volume of 100 μ L) for 5 min at 65 °C followed by cooling on ice for 5 min. This template was added to the transcription mixture (10 mL), which is 40 mM Tris•HCl buffer, pH 8.1, containing rNTPs (4 mM each), GMP (8 mM), magnesium chloride (25 mM), spermidine (1 mM), DTT (5 mM), Triton X-100 (0.01 %, v/v), Prime RNase Inhibitor (10 μ L, 10 U), and inorganic pyrophosphatase (5 μ L, 5 U). The *in vitro* transcription reaction was initiated by adding T7 RNA polymerase (25 μ L, 25000 U) and incubated for 9 h at 37 °C. [64] Urea-PAGE analysis was used to monitor the reaction progress. Periodically, an aliquot (3 μ L) of the reaction mixture was withdrawn and diluted with water (10 μ L final volume); 2x RNA loading dye (10 μ L) was added, and the sample was then heated for 5 min at 94 °C, cooled on ice for 5 min, and loaded on to a urea-PAGE gel (15%, 7M urea). The transcription products were visualized with SYBR[®] Gold nucleic acid stain.

After analysis showed no further accumulation of TSL, TURBO[™] DNase (5 μ L, 10 U) was added to the transcription reaction, which was incubated for an additional 15 min at 37 °C. Proteins were extracted from the reaction mixture with 1:1 phenol:chloroform. The crude RNA in the collected aqueous phase was precipitated with ethanol and pelleted by centrifugation (8000g, 30 min). The pelleted RNA was washed with aqueous ethanol (70%, v/v), air dried, and dissolved in 10 mM Tris•HCl buffer, pH 7.5, containing EDTA (1 mM).

The transcript of interest (18-mer) was purified from the crude mixture by urea-PAGE electrophoresis (15%, 7M urea; 15 cm $\times$ 15 cm). The crude transcript

(1 mL) was mixed with 2x RNA dye (1 mL), heated for 5 min at 94 °C, cooled on ice for 5 min, and loaded onto the gel. After being developed at 165 V for 6 h, the gel was removed, and the band of interest was located by UV-shadowing. RNA was extracted from the excised band either by electroelution using an Elutrap electrophoresis unit (GE Healthcare; Pittsburgh, PA) run at 200 V for 3 h, or by the crush and soak method. [98] RNA was ethanol-precipitated, pelleted by centrifugation (8000g, 30 min), and redissolved in RNase free water. Purified TSL was divided into aliquots and stored at -20 °C.

Labeled TSL. The labeled transcript was prepared identically to the unlabeled transcript, except that [2'-²H]UTP (4 mM) was substituted for UTP.

ASL. The *in vitro* transcription of ASL with UTP and [2'-²H]UTP was identical to the synthesis of TSL except for the template, which was composed of 5'-GCGGATTTTCAATCCGCTATAGTGAGTCGTATTA-3' (underlining indicates the complement to ASL) and 5'-TAATACGACTCACTATAGC-3'.

Digestion of transcripts and MALDI-MS

An aliquot of the RNA oligonucleotide (10 µL, 80-100 µM) was diluted into RNase-free water (40 µL) to which RNase T1 (2 µL, 200 U) was added. After incubation for 1 h at 37 °C, alkaline phosphatase (5 µL, 5 U) was added to the digestion mixture, which was incubated for an additional 3 h at 37 °C. An aliquot (3 µL) of the digest was mixed with 3-HPA matrix solution (3 µL), which was 3-hydroxypicolinic acid (3-HPA; Fluka, Milwaukee, WI; 10 mg/ml) in 50% aqueous acetonitrile. The sample was spotted on a MALDI plate, air dried, and analyzed on a Voyager DE-Pro MALDI-TOF instrument or an API 4700 MALDI-TOF Mass

spectrophotometer (PE Biosystems, Foster City, CA). Spectra were acquired and analyzed as described in Chapters 2 and 3.

Kinetic assays

The enzymes TruB and RluA were overexpressed, purified, and assayed using published protocols. [30, 64] For TruB, the standard reaction buffer was 50 mM HEPES buffer, pH 7.5, containing ammonium chloride (100 mM), EDTA (1 mM), and DTT (5 mM). [64] The reaction mixtures (400-2600 μ L) were standard reaction buffer containing TSL (1-10 μ M). After pre-incubation for 3 min at 37 °C, reactions were initiated by the addition of a small volume (<2 μ L) of TruB (to 10 nM). Aliquots (75-650 μ L) were removed at various time intervals and quenched into pre-heated (100 °C) tube containing 10x S1 nuclease digestion buffer (1/10th the volume of aliquot), which is 300 mM sodium acetate buffer, pH 4.6, containing sodium chloride (500 mM), zinc chloride (100 mM), and glycerol (50%, v/v). After another 5 min in a boiling water bath, the tubes were cooled on ice for 5 min. S1 nuclease (0.5 μ L, 50 U) was added, and the mixture was incubated for 1 h at 37 °C; the digest was then incubated for 5 min at 94 °C followed by incubation on ice for 5 min. Another aliquot of S1 nuclease (1 μ L, 100 U) and alkaline phosphatase (3 μ L, 3 U) were added, and the mixture was incubated for 3 h at 37 °C. The digest was then passed through a Corning Costar™ spin filter (0.22 μ m), and analyzed over an SB-C18 analytical column connected to Beckman Coulter System Gold HPLC (Indianapolis, IN) equipped with a Model 168 programmable diode array detector module.

For RluA, the previously reported assay procedure [30] was modified because, unlike commercially–obtained ASL^U (a 17-mer), the *in vitro* transcribed ASL^U (an 18-mer) was not readily separable from ASL^Ψ. To quantify Ψ, the 18-mer ASL was digested to its component nucleosides and analyzed by HPLC. The assay mixtures (450-2400 μL) were standard reaction buffer containing ASL (1-10 μM). After pre-incubation for 3 min at 37 °C, reactions were initiated by the addition of a small volume (<2 μL) of RluA (to 10 nM). Aliquots (100-600 μL) were removed at various time intervals and quenched and analyzed as described above for TSL.

Results

Enzymes for the synthesis of [2'-²H]UTP

The plasmid encoding ribokinase (pET-22HT) showed poor levels of overexpression, and the activity of the overexpressed enzyme was low. DNA sequencing revealed insertions at both the ends of *rbsK*. To rectify these errors, NdeI and BamHI restriction sites were introduced on to the 5'- and 3'-ends of *rbsK* by PCR. This allowed both the restoration of the native gene by eliminating the insertions and a means to install *rbsK* in pET-15b. Use of this recombinant plasmid (pUL600) resulted in improved levels of expression for ribokinase (Figure 4.7). PRPP synthetase and UPRTase were expressed without incident. Assays revealed that all three enzymes had specific activities comparable to literature values (Table 4.1).

Synthesis of [2'-²H]UTP

Because [2'-²H]UTP is commercially unavailable, it was synthesized by the enzymatic condensation of [2'-²H]D-ribose and uracil (Figure 4.9) according to the method of Williamson. [91, 92] The first step of this one pot synthesis involves phosphorylation of [2'-²H]D-ribose by ribokinase. PRPP synthetase then converts [2'-²H]D-ribose-5-phosphate into [2'-²H]PRPP which is converted into [2'-²H]UMP by UPRTase. [2'-²H]UDP results from phosphorylation at the expense of ATP by nucleoside monophosphate kinase, following which [2'-²H]UTP is generated by pyruvate kinase at the expense of PEP.

The overall synthesis minimally requires four equivalents of ATP, which was continuously generated *in situ* at the expense of PEP using pyruvate kinase and myokinase. To avoid buildup of ADP, the activity of myokinase was half that of pyruvate kinase.

After the synthesis of [2'-²H]UTP was complete as judged by ³¹P NMR and pyruvate assay, purification was achieved in three steps. The enzymes used in the synthesis were removed by ultrafiltration. More than 90% of PEP, inorganic phosphate, and pyruvate in the reaction mixture were removed by the adsorption of [2'-²H]UTP and ATP onto charcoal, rinsing, and elution in aqueous ethanol. The [2'-²H]UTP was freed of contaminating ATP and PEP by solid phase extraction over a Bond Elut C8 SPE cartridge. [2'-²H]UTP (167 μmol, 46% yield) was obtained at >95% purity as judged by NMR spectroscopy (Figures 4.10, 4.11, and 4.12).

***In vitro* transcription**

Unlabeled and labeled stem-loop RNA substrates for TruB and RluA were prepared by run-off *in vitro* transcription using T7 RNA polymerase. The template and rNTP concentrations and time were optimized because transcription efficiency is highly sensitive to them depending on the length of the RNA being transcribed. [99] The transcription of these short stem-loops required a higher concentration of DNA template (0.5 μ M) and a longer incubation (9 h) when compared to the transcription of full length tRNA. [64]

TSL. The original *S. cerevisiae* T-arm stem-loop tRNA^{Phe} (TSL) substrate is a 17-mer that starts with a 5'-Cytidine. For efficient transcription, T7 RNA polymerase requires G as the initial nucleotide. Therefore, two TSL transcripts of lengths 18 (5'-G added to canonical TSL) and a 19-mer (5'-GG added) were tested for *in vitro* transcription and obtained in comparable yields (9 μ mol 18-mer versus 11 μ mol 19-mer). When these transcripts (5 μ M) were incubated with *E. coli* TruB (0.5 μ M) in standard reaction buffer for 1 h at 58 °C, analysis of the digested nucleosides by reverse phase HPLC showed complete conversion for both transcripts, showing their competence as substrates. In aliquots withdrawn after 1 min, the 18-mer (64.5%) showed greater conversion of U to Ψ than the 19-mer (52.0%), so the 18-mer RNA was chosen for large-scale transcription (10 mL). Once trials determined optimal *in vitro* transcription conditions, UTP and [2'-²H]UTP were used in separate transcription reactions to generate unlabeled and labeled 18-mer TSL (Figure 4.13), which will hereafter be termed TSL for simplicity.

ASL. The anticodon-stem-loop from *E. coli* tRNA^{Phe} (ASL) starts with a string of four Gs (Figure 4.14, panel A), which in principle eliminates the need to alter the 5'-end. However, small scale transcription revealed in a “ladder” of transcription products rather than a single one (Figure 4.14, panel C). Literature review [100, 101] revealed that T7 RNA polymerase undergoes “slippage” when transcribing RNA containing a stretch of three or more Gs, which is the case with ASL. This issue was addressed by designing a DNA template that would instead transcribe ASL with a reversed C-G base pair at the second position (Figure 4.14, panel B and C). This change resulted in a single transcription product. UTP and [2'-²H]UTP were used in separate large scale transcription reactions to afford labeled and unlabeled variant ASL, which will hereafter be termed ASL for simplicity (Figure 4.14).

Sequence verification of transcripts

The sequences of unlabeled and labeled TSL and ASL transcripts were verified by digestion with RNase T1 and analysis by MALDI-TOF mass spectroscopy. The digestion products containing [2'-²H]U showed a corresponding increase in the *m/z* value when compared to their unlabeled counterparts (Figure 4.15 and 4.16).

Kinetic assays

TruB was assayed under conditions used previously. [64] The efficacy of the quench methodology was verified by analyzing time points for each assay immediately after addition of TruB to initiate the reaction. Because intact TSL^U did not separate from intact TSL^Ψ, the product RNA was digested to individual nucleosides to quantify Ψ formation. The assays for the labeled and unlabeled substrates were performed at variable substrate concentrations as described in the Experimental section. The data was then fit to Briggs-Haldane equation (Figure 4.17) to determine the k_{cat} and K_m values, which revealed significant ²KIEs (Table 4.2) on both V_{max} ($^2V_{max} = 2.54$) and K_m ($^2(V_{max}/K_m) = 3.58$).

The assay for RluA was similar to that of TruB. The reaction quench methodology and the reverse phase HPLC-based quantification of ASL^Ψ were different from those previously reported [30] because the *in vitro* transcribed ASL^U failed to separate from the intact ASL^Ψ. The assays for the labeled and unlabeled substrates were performed at different substrate concentrations and the initial velocity data was then fit to the Briggs-Haldane equation (Figure 4.18). The determined k_{cat} and K_m values revealed a ²KIE (Table 4.2) on both V_{max} ($^2V_{max} = 1.79$) and K_m ($^2(V_{max}/K_m) = 2.17$).

labeled ASL	7.773 ± 0.745	1.594 ± 0.691		

Discussion

To obtain definitive evidence for glycol intermediate formation during the conversion of U to Ψ , ^2KIE were measured. TSL and ASL were prepared by synthesizing $[2'\text{-}^2\text{H}]\text{UTP}$ and incorporating it into RNA by *in vitro* transcription.

Subcloning, overexpression and purification

The overexpression of PRPP synthetase and UPRTase posed no problems. The specific activities of the purified enzymes were similar to literature values (Table 4.1). [95] However, the plasmid encoding ribokinase (pET-22HT) [91] afforded poor levels of overexpression of barely active enzyme (Table 4.1). DNA sequencing revealed an overhang after the stop codon and an inverted duplication towards the 5'-end. These errors were rectified by introducing NdeI and BamHI restriction sites on to the immediate 5'- and 3'-ends of *rbsK* to allow the precise placement of *rbsK* into pET-15b to overexpress ribokinase with an N-terminal His₆•tag. The specific activity of the ribokinase thus obtained mildly exceeded the published value (Table 4.1). [95]

With the enzymes in hand, $[2'\text{-}^2\text{H}]\text{UTP}$ was synthesized enzymatically (Figure 4.9). The synthesis requires at least 4 equivalents of ATP per equivalent of $[2'\text{-}^2\text{H}]\text{UTP}$ being formed, but high concentrations of ATP could not be directly used in the synthesis because released ADP would inhibit ribokinase and PRPP synthetase. These issues were addressed by *in situ* regeneration of ATP at the expense of PEP using pyruvate kinase and myokinase. The use of excess PEP drove $[2'\text{-}^2\text{H}]\text{UTP}$ synthesis to completion. However, the separation of the

synthesized [2'-²H]UTP from residual PEP and the by-product pyruvate presented a challenge. Charcoal adsorption proved a simple but effective means to separate [2'-²H]UTP from PEP and pyruvate. Finally, [2'-²H]UTP was separated from ATP by solid phase extraction over a C₈ matrix.

***In vitro* transcription**

Run-off transcription with T7 RNA polymerase is a convenient route to short oligonucleotides. [99, 102] The DNA sequence complementary to the required RNA product is placed downstream of the T7 promoter, which must be double-stranded for T7 RNA polymerase to bind. Efficient transcription requires G as the first transcribed nucleotide (the +1 position). For the *in vitro* transcription of TSL (Figure 4.13, panel A), an extra G was introduced on to the 5'-end for this purpose because the canonical TSL used in earlier studies of TruB [29, 52] starts with a C.⁷ The canonical ASL used previously [30] begins with a run of four Gs, which sometimes causes the polymerase to “slip” back by one nucleotide, resulting in a “ladder” of transcripts. This phenomenon was apparent during the transcription of canonical ASL (Figure 4.14, panel A). Therefore, ASL was modified (Figure 4.14, panel B) by reversing the second base pair in the stem loop, which resulted in the sequence: 5'-GCGGAUUGAAAAUCCGC-3' (underlined regions represent the swapped nucleotides of the stem loop; Figure 4.13, panel B).

The concentration of rNTPs, template DNA, T7 RNA polymerase, and the length of the reaction incubation play an important role in obtaining good yields of

⁷ It is the T-arm of *S. cerevisiae* tRNA^{Phe} and prepared by chemical synthesis rather than the *in vitro* transcription.

transcripts. The slow step in transcription is initiation, which is directly affected by the concentration of rNTPs and T7 RNA polymerase. T7 RNA polymerase also tends to produce abortive transcripts 3-12 nucleotides in length before switching into its harder processive mode, so there is a chance for the depletion of the rNTPs of nucleotides abundant in the initial part of the transcript. [99, 102] In the transcription of oligonucleotides shorter than 20-mers, a higher concentration of DNA template (0.5-1 μ M) and T7 RNA polymerase (2500 U/ml) yield better results [99, 102] because of the increase in the number of transcription initiation events. All of these considerations went into the optimization of conditions to maximize the yield of transcript with precious [2'- 2 H]UTP. The optimized conditions yielded sufficient TSL and ASL (both labeled and unlabeled) for the kinetic studies, and the sequence of the purified transcripts were verified by digestion with RNase T1 and analysis by MALDI-TOF mass spectrometry.

Deuterium kinetic isotope effect studies

A deuterium kinetic isotope effect (2 KIE) is the observed change in rate of a chemical reaction when one of the protons in the reactants is substituted with a (heavier) deuteron. Kinetic isotope effects arise from differences in zero-point energy levels for the isotopologues of interest in the ground and transition states (Figure 4.19). [88, 103] In the case of “a proton in flight” (a primary KIE), there is no zero-point energy difference at the transition state for proton transfer, so the lower zero-point energy level of deuterium *versus* protium translates in to a larger activation energy barrier for the heavier isotope and hence a decreased reaction rate. In this classical analysis, the zero point energy difference between protium

and deuterium dictates a maximum value of 6.9 for a primary ^2KIE , [88] but larger effects are seen when tunneling is involved because of the substantially short de Broglie wavelength of a deuteron ($0.45 \text{ \AA}$) *versus* a proton ($0.63 \text{ \AA}$). [88] A secondary effect arises when the deuterium remains bonded throughout the reaction to a carbon atom that undergoes a change in hybridization. The differences in the energy of bond bending modes between sp^2 and sp^3 centers impose a maximum theoretical value of 1.4 for a secondary ^2KIE . [88]

For TruB with unlabeled TSL, $k_{\text{cat}} = 0.337 \pm 0.025 \text{ s}^{-1}$ and $K_{\text{m}} = 1.334 \pm 0.318 \text{ }\mu\text{M}$, values in agreement with those reported previously ($k_{\text{cat}} = 0.24 \text{ s}^{-1}$, $K_{\text{m}} = 0.8 \text{ }\mu\text{M}$). [29] These observations suggest that the *in vitro* transcribed TSL serves as an excellent substrate for TruB despite the addition of an unpaired 5'-G. The observed ^2KIE on V_{max} (2.54) and $V_{\text{max}}/K_{\text{m}}$ (3.58) indicate that deprotonation or reprotonation of C2' (or both) is partially rate limiting and **provide direct evidence for the operation of glycal mechanism** (Figure 4.3) during the conversion of U to Ψ .

RluA was chosen to test the generality of this finding with another family of Ψ synthases. The k_{cat} ($0.558 \pm 0.010 \text{ s}^{-1}$) and K_{m} ($1.32 \pm 0.42 \text{ }\mu\text{M}$) with the *in vitro* transcribed ASL with a reversed base pair in the stem were some 8-fold higher than those previously reported ($k_{\text{cat}} = 0.067 \pm 0.003 \text{ s}^{-1}$, $K_{\text{m}} = 308 \pm 66 \text{ nM}$) with canonical ASL, [30] indicating that this “new” ASL is an efficient substrate. Primary $^2\text{KIEs}$ were observed for V_{max} (1.79) and $V_{\text{max}}/K_{\text{m}}$ (2.17), again indicative of the operation of the glycal mechanism. These results with RluA cemented the observations with TruB, thereby providing unambiguous evidence for a glycal

intermediate in the operation of two Ψ synthase families and thus, by implication, for all Ψ synthases.

Overall conclusions

Three different mechanisms have been proposed for Ψ synthases, and they all involve the conserved Asp acting as either a nucleophile or a base. [36, 43] In the 'Michael mechanism' (Figure 4.1), the conserved Asp acts as a nucleophile to attack C6 of the pyrimidine ring to form a Michael adduct. This mechanism was based on findings with TruA, which upon incubation with [F⁵U]RNA gets irreversibly inhibited and appears in an adduct band on denaturing PAGE gels.[36] The 'acylal' mechanism (Figure 4.2) instead proposes a nucleophilic attack at the C1' of the ribose ring by the conserved Asp. Studies with TruB provided more mechanistic clues into the action of Ψ synthases. Whereas TruA and RluA form adducts when incubated with [F⁵U]RNA, TruB does not, nor does it get inhibited by [F⁵U]RNA but instead converts F⁵U into two rearranged and hydrated products that differ in stereochemistry at C2'. [25, 43]

¹⁸O labeling studies with TruA, TruB, RluA, TruD and TmTruB [30, 41, 42, 67] all show that the hydration of the products of F⁵U occurs directly from solution and not through the hydrolysis of a Michael adduct. A consistent scheme was then proposed by Mueller and co-workers for the hydration of F⁵U, and it has been slightly revised to accommodate the *arabino* product of F⁵U (Figure 2.23). By any mechanism, the Ψ synthases rearrange F⁵U, and idiosyncracies of the active site dictate its fate. In some active sites (TruA and RluA), the conserved Asp or some other nucleophile in the active site can reach C6 to make a stable adduct. The adduct, upon heating, undergoes elimination (rather than ester hydrolysis), followed by the spontaneous hydration of the rearranged F⁵U in solution. [30, 41]

In other active sites (TruB, for example), the conserved Asp does not form a stable adduct with the pyrimidine, so the rearranged F⁵U is simply released into solution followed by hydration. This proposed scheme for hydration is consistent with TmTruB, which reversibly forms an adduct when incubated with [F⁵U]RNA: after rearrangement, the C-glycoside of F⁵U either gets trapped (whether by the conserved Asp or some other active site residue) or gets released into solution, where it becomes hydrated. The cocrystal structure of RluB with [F⁵U]RNA [46] shows a covalent bond between the hydroxyl group of Tyr-146 and the pyrimidine ring of F⁵U, which is also consistent with the scheme that proposes the trapping of the rearranged F⁵U.

Structural elucidation of the products of F⁵U by Miracco and Mueller [43] revealed that the major (*ribo*) and minor (*arabino*) products of F⁵U differ in their stereochemistry at C2', which requires epimerization through the formation of a glycal intermediate. Either the conserved Asp or O² of the pyrimidine ring can deprotonate C2' to form the glycal intermediate, and reprotonation of C2' from the "bottom" face yields the *arabino* product of F⁵U. The existence of the *arabino* product strongly disfavors the Michael mechanism because the conserved Asp is tied up in an ester bond during the crucial deprotonation/reprotonation of C2'. If O² instead deprotonates the C2' by acting as a base, [87] the Michael mechanism may still be valid if solvent reprotonates C2'. However, the lack of deuterium wash-in for TruB and RluA with RNA containing U and F⁵U discredits this hypothesis. [67] These results also favor the conserved Asp as the base for the deprotonation step because it gets the conserved Asp into its acid form to reprotonate C2' from

the 'bottom' face. A variation of the Michael mechanism that can account for the *arabino* product would be the formation of the Michael adduct by the active site tyrosine residue, which would result in the conserved Asp remaining free to deprotonate and reprotonate C2'. The Ψ synthases share a conserved aromatic amino acid residue, which is a tyrosine in five of the six families (this Tyr-146 residue is adducted with [F⁵U]RNA in the RluB cocrystal). However, this hypothesis can also be discredited for several reasons. The fully functional TruD family has non-nucleophilic phenylalanine residues in this conserved position. [48-50] Huang and co-workers found that substitution of this tyrosine residue in TruB with phenylalanine, leucine, or alanine resulted in an enzyme that can no longer handle the natural substrate (with U) but can handle [F⁵U]RNA to rearrange and hydrate F⁵U. [51] If the tyrosine residue forms the initial Michael adduct, these variants should have left both U and F⁵U unchanged (if the adduct does not form, no rearrangement to the C-glycoside should occur). Finally, the pH profile of TruB suggests that the active site tyrosine residue functions in its protonated form and thus is better suited to assist the *N*-glycosidic bond cleavage of the uridine, by donating either a proton or hydrogen bond to the pyrimidine ring. [26, 52] Cleavage of F⁵U at the *N*-glycosidic bond does not require the assisting tyrosine residue because the inductive effect of fluorine creates a better leaving group than with uridine.

The *arabino* product of F⁵U can be explained as part of the acylal mechanism (Figure 3.2). The decreased nucleophilicity of the fluorouracilate anion provides a longer lifetime for the acylal and oxocarbenium intermediates, thereby

allowing them to access an alternate reaction pathway. The increased acidity of C2' in the oxocarbenium allows its deprotonation by the conserved Asp to form a glycal intermediate. Reprotonation of C2' from the “bottom” face would then result in the *arabino* product of F⁵U.

The existence of a glycal intermediate along the reaction pathway of F⁵U opens up a new mechanistic possibility, the ‘glycal’ mechanism (Figure 4.3) in which the glycal intermediate forms during the conversion of U to Ψ. The low levels of deuterium wash-in observed in the F⁵U products with both wild-type and Y76L TruB (undetectable and <4.5%, respectively) indicate that the conserved Asp is sequestered from solvent on the time scale of conversion of F⁵U to its products and are consistent with a glycal intermediate along the F⁵U reaction pathway (whether it is the acylal mechanism, or glycal mechanism that operates).

The observed primary ²KIE with TruB and RluA for U to Ψ unambiguously indicates the operation of the glycal mechanism for these two Ψ synthases from different families. The active sites of all six families have several conserved residues along with the absolutely conserved Asp that is essential for activity, [9, 10, 24-27] which strongly suggests that they all operate through a single mechanism, namely the ‘glycal’ mechanism.

CURRICULUM VITAE

Govardhan reddy Veerareddygari

EDUCATION

Ph. D. in Chemistry, Anticipated Graduation Date: October-December 2014

Dissertation: Mechanistic investigations of Pseudouridine synthases

University of Louisville (2008-Present)

Louisville, KY.

M.S. in Chemistry

Thesis: Mechanistic investigations of Pseudouridine synthases

University of Louisville (2012)

M.Sc in Biophysical Chemistry

University College of Science,

Osmania University,

Andhra Pradesh, India (2004-2006).

Areas of Concentration: Chemistry and Biology

AWARDS AND HONORS

- Graduate Research Assistantship at University of Louisville (2013-present)

- Graduate Teaching Assistantship at University of Louisville (2008-2012)
- Gold medal at University college of Science for excellence in the field of Biophysical Chemistry

RESEARCH SKILLS

- Experienced in handling RNA, purification and desalting using HPLC, *In Vitro* transcription of RNA using T7 RNA polymerase, qualitative and quantitative analysis of RNA by UV-Vis and HPLC.
- Modified pre-existing methods and successfully implemented one-pot enzymatic synthesis of isotopically labeled nucleotide triphosphates for downstream usage in *In Vitro* transcription of labeled RNA oligonucleotides.
- Hands-on experience in organic synthesis (nucleotide phosphoramidite micro scale synthesis for downstream use in the synthesis of labeled RNA oligonucleotides) with running reactions under anhydrous conditions, extractions, separation of compounds using high vacuum distillation, and analysis using GC-MS, TLC and NMR (1D and 2D) (micro scale).
- Successfully designed, handled and completed research projects that involve enzyme kinetics with RNA substrates, recombinant DNA technology, cell culture, recombinant protein overexpression, purification and characterization.
- Highly experienced in handling instruments such as HPLC, GC, GC-MS, MALDI-TOF Mass Spectrometry, UV-Vis, NMR and FPLC. Efficient in successfully designing and executing new analytical methods, qualitative and quantitative analysis of data, compiling reports and presentations.

- Skilled with using analytical software such as Kaleidagraph®, mMass®, ChemDraw®, SciFinder®, MestreNova®, Endnote®, and various other software including Microsoft Office®, Adobe Illustrator®, Adobe Photoshop®. Proficient in using online databases such as SciFinder to compile relevant scientific data to support research needs.

RESEARCH AND PROFESSIONAL EXPERIENCE

Graduate Research (Fall 2008- Present)

Department of Chemistry, University of Louisville, Louisville KY

- Mechanistic investigations of a thermophilic pseudouridine synthase, *Thermotoga maritima* TruB (TmTruB) (2009-2013).
- Mechanistic investigations of a pseudouridine synthase *Escherichia coli* TruB (EcTruB) (2011).
- Kinetic isotope effects as a means to study the mechanism of pseudouridine synthases (2012-2014).

Chemistry Graduate Student Association (CGSA)-Secretary (Fall 2010- Spring 2012)

Department of Chemistry, University of Louisville, Louisville KY

- Secretary (2010 – 2012). Organization and coordination of the banquets and hospitality events for the distinguished **Nobel Laureates** that were invited to speak at the University
- Host of the Annual Distinguished Lecturer Series.
 - 2012 Richard R Schrock (2005 Nobel Prize in Chemistry)
 - 2011 Ei-ichi Negishi (2010 Nobel Prize in Chemistry)

- Organizing fun activities for graduate students, and act as a liaison for all Chemistry Graduate Students to the University GSA, and faculty.

Teaching Assistant- CHEM 546 Bio Chemistry (Spring 2009, Fall 2010-12)

Department of Chemistry, University of Louisville, Louisville KY

- Demonstration and supervision of course syllabus for each lab section. Responsibilities included knowledge of course content, hands on experience with the biochemical methods.
- Provided students with practical, hands-on experience in contemporary biochemical methods (uv/vis spectrophotometry, liquid chromatography, centrifugation, gel electrophoresis, 2D-NMR, matrix-assisted laser-desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), and DNA methods) with a discovery-based approach.

Teaching Assistant- CHEM 445 Survey of Bio Chemistry (Spring 2011-13)

Department of Chemistry, University of Louisville, Louisville KY

Learning objectives of the following course include,

- To understand biological processes and concepts from the chemical perspective.
- To effectively find, learn, and apply relevant biochemical knowledge.
- To critique biochemical information from a variety of sources including peer reviewed journal articles and determine the information's reliability, significance, and applicability to specific problems.

Teaching Assistant- CHEM 341 Organic Chemistry (Summer 2010)

Department of Chemistry, University of Louisville, Louisville KY

- An introductory organic chemistry laboratory course that teaches undergraduate students the basic techniques of organic synthesis.

Teaching Assistant- CHEM 103 General Chemistry (Spring 2012-13)

Department of Chemistry, University of Louisville, Louisville KY

- An introductory chemistry laboratory course that will allow freshmen undergraduate students experience and explore chemical phenomena.

POSTERS AND PRESENTATIONS

Oral Presentation (October 2014)

The 34th Midwest Enzyme Chemistry Conference, Northwestern University, Evanston, IL

- “A primary 2'-deuterium kinetic isotope effect indicates that pseudouridine synthases proceed through a glycol intermediate” **Govardhan reddy Veerareddygar**i and Eugene G. Mueller.

Poster Presentation (July 2014)

Enzymes, Coenzymes and Metabolic pathways, Gordon Research Conferences, Waterville Valley, NH

- “Mechanistic studies of the Pseudouridine synthase *Thermotoga maritima* TruB” Govardhan reddy Veerareddygar*i* and **Eugene G. Mueller**.

Poster Presentation (March 2013)

The Institute for Molecular Diversity and Drug Design Symposium, Jewish Hospital and St. Mary's HealthCare, Louisville KY

- “Mechanistic investigations of a Pseudouridine synthase *Thermotoga maritima* TruB (TmTruB)-2” **Govardhan reddy Veerareddygar**i and Eugene G. Mueller.

Poster Presentation (March 2012)

The Institute for Molecular Diversity and Drug Design Symposium, Jewish Hospital and St. Mary's HealthCare, Louisville KY

- “Mechanistic investigations of a Pseudouridine synthase *Thermotoga maritima* TruB (TmTruB)-1” **Govardhan reddy Veerareddygari** and Eugene G. Mueller.

Poster Presentation (March 2012)

Rustbelt RNA Meeting (RRM), Dayton, OH

- “The initial kinetic characterization of a thermophilic pseudouridine synthase (*Thermotoga maritima* TruB)” **Govardhan reddy Veerareddygari** and Eugene G. Mueller.

Poster Presentation (June 2012)

Göttingen, Germany

- “Looking for an intermediate: Wash-in studies to probe the Pseudouridine synthase reaction” **Eugene G. Mueller**, Edward J. Miracco, Sanjay K. Singh and Govardhan reddy Veerareddygari

MEMBERSHIPS

- Institute of Molecular diversity and drug design (IMD3) (March 2010-present)
- Rustbelt RNA society (2010-present)
