IDENTIFYING HEPATOCELLULAR CARCINOMA (HCC) CELLS WITH CANCER STEM CELL-LIKE PROPERTIES

By

Harshulkumar M. Pandit

A Thesis Approved on

April 17, 2015

By the following Thesis Committee:

Robert C.G. Martin II, MD, Ph.D., FACS

David Hein, Ph.D.

Aruni Bhatnagar, Ph.D.

Haribabu Bodduluri, Ph.D.

Yong Li, Ph.D.

ACKNOWLEDGEMENTS

I would like to sincerely thank my mentor, Dr. Robert C.G. Martin, for providing his insights, guidance, encouragement, and offering me this valuable and amazing opportunity to work in his lab in the field of Hepatocellular Carcinoma (HCC). I would also like to express my deepest gratitude to Dr. Yan Li, who provided invaluable help and continuous support on every step of this project. My gratitude also goes to my committee members, Dr. David Hein, Dr. Aruni Bhatnagar, Dr. Haribabu Bodduluri, and Dr. Yong Li for their valuable feedback and assistance. A special thanks to my lab-mates, Suping Li, Dr. Gordon Cui, Dr. Zhang, Saline Li, and the rest of the Martin lab for making my time in the lab enjoyable and for helping me when I needed it. I am also very grateful to my wife, Reema, my parents, my family, and my friends for their love and continuous support.

ABSTRACT

IDENTIFYING HEPATOCELLULAR CARCINOMA (HCC) CELLS WITH CANCER STEM CELL-LIKE PROPERTIES

Harshulkumar M. Pandit

April 17, 2015

Hepatocellular Carcinoma (HCC) is a challenging condition to treat in the clinic due to its distinct tumor phenotype, aggressive growth, and chemotherapy resistance. Cancer Stem Cells (CSCs) are a poorly differentiated subpopulation of cells within the tumor microenvironment, and role of CSCs in tumor initiation and chemotherapy resistance is not well understood in HCC. In this study, we have successfully identified HCC cells with CSC-like properties that showed resistance to Doxorubicin. Using the established serum free culture techniques, we have enriched CSC-like cells among hepatocellular cancer cells. These enriched cells exhibit all CSC-like properties i.e. self-renewal capability, anchorage independent growth with retained proliferation property and resistance to Doxorubicin. We confirmed expression of CSC surface markers (EpCAM, CD90, CD44, CD133) and functional markers (ALDH activity and dye exclusion properties) in enriched HCC-CSCs. Preliminary *in vivo* data in our mouse

models supports that spheroid forming CSCs show higher rate of tumor proliferation compared to untreated (non-spheroid forming) HCC cells. Wnt/ β -catenin pathway components were also found to be overexpressed in CSCs when compared to non spheroids. Analysis of 24 paired human specimens from HCC tissues by IHC showed higher EpCAM expression, and Western Blot analysis suggested concomitant changes in β -catenin and EpCAM levels. In conclusion: (1) we have successfully induced and identified HCC cells with CSC-like properties; (2) Aberrant β -catenin up-regulation mediated Wnt/ β -catenin signaling activation was observed in enriched hepatoma spheroids.

CHAPTER I

INTRODUCTION

Hepatocellular Carcinoma (HCC):

HCC, also referred to as hepatoma, is a type of epithelial cancer in liver, and most common form of liver cancers in adults, usually age 50 or older. HCC is the fifth most common cancer in men and seventh in women worldwide, and accounts for the third major cause of cancer related deaths worldwide [1]. HCC has different growth patterns, and the most common growth pattern seen in the United States is development of HCC secondary to cirrhosis (chronic liver damage), where HCC typically starts as several small cancer nodules at multiple sites in the liver than just a single large tumor. Men are two to four times more likely to develop liver cancer than women. Reports have suggested that 80-90% of primary liver cancer incidences in the United States are HCC [1, 2]. A 2013 CDC report has suggested that liver cancer related deaths in US men is increasing at rate of 2% per year despite better success rates in other cancers [1].

Risk Factors, Diagnosis and Treatment Modalities:

Major known risk factors for HCC are cirrhosis, Hepatitis B virus (HBV) or Hepatitis C virus (HCV) infection, alcoholic liver disease, and non-alcoholic fatty liver disease (NAFLD) [2]. Newly added risk factors are obesity and type-II Diabetes for development of HCC[3, 4]. A recent policy statement by American Society of Clinical Oncology (ASCO) reported that obesity will overtake tobacco as the leading cause of cancer in near future [5]. In HCC patients, distribution of these risk factors are highly variable, depending on ethnic groups and geographic regions [6]. Most of these risk factors lead to cirrhosis or its progression, which is present in 80-90% of HCC patients. According to a study by fattovich et al., the 5 year cumulative risk for HCC development in cirrhosis patients ranges between 5% and 30% globally, 18% in the United States, depending on cause, ethnic group, and stage of cirrhosis [7]. As a result of the variety of causes and risk factors for HCC, patients show vast diversity in clinical presentation and disease progression, compared to any other solid malignancies.

Treatment options following initial diagnosis is based on staging guidelines. Standard means of assessing prognosis of HCC patients is Barcelona Clinic Liver Cancer (BCLC) staging system and Child-pugh classification system [8]. Recommended treatment options for HCC patients are surgical resection of tumors, liver transplantation, local ablation, chemotherapy (Doxorubicin), trans-arterial chemoembolization (TACE) (Doxorubicin), radioembolization, and targeted molecular therapy (Sorafenib). Prognosis and disease free survival is subjective to individual patient and treatment options. Although, we have gained

scientific advances in diagnosis and treatment modalities, HCC is still considered difficult to treat because of its late presentation, chemotherapy resistance, and high recurrence rate [9].

Cancer Stem Cell (CSC) Model and HCC:

Our view of carcinogenesis and chemoresistance has changed since the discovery of Cancer Stem

Cells (CSC) or Tumor Initiating Cells (TIC) [10, 11].

Understanding that tumor development and growth is not only maintained by selection of genetically mutated population

of cells (Stochastic model), but also by the tumor microenvironment which facilitates communication between altered tumor cells and their unaltered neighbors like fibroblasts, endothelial cells, and inflammatory cells [12]. CSCs are a small population of less differentiated cells within the tumor microenvironment which possess stem-cell like properties i.e. self-renewal capability and ability to differentiate into heterogeneous lineages of cancer cells via asymmetric division [10]. CSC model proposes hierarchical organization, where apex CSC retains self-renewal capability with highest tumorigenic potential (Figure-S2), while bottom most differentiated cancer cells lose this important stem-ness property and become less tumorigenic [10, 13]. Lapidot et al. proposed the CSC hypothesis for the first time in primary human acute

myeloid leukemias (AMLs) in 1994 [14]. A study on breast cancer by Al-Hajj et al. was the first to report evidence of CSCs in solid tumor [15]. Since then, several studies have been reported presence of CSCs in solid tumors like colon [16], pancreas [17], and liver [18-20]. The first direct evidence to support CSC theory came from lineage-tracing study by Barker et al. in 2007, where they studied tracing of Lgr5+ cells in development of small intestine and colon tumors in genetically engineered mice [21]. In 2012, two more groups had published lineage-tracing studies in genetically engineered mouse models [22, 23].

Several groups have studied role of CSCs in HCC and reported their clinical significance [24, 25]. The CSC tumor model has been proven to show clinical relevance in primary HCC and HCC recurrence [25-27]. Haraguchi et al. identified a subset of stem cells, “side population” (SP) cells, in Huh-7 and Hep3B cell lines which highly express multi-drug resistant ABC-transporters [28]. Ma et al. and colleagues have shown that sorted SP cells possess high stemness gene expression and higher tumorigenicity [26, 27]. Using tumorigenicity potential and stemness characteristics as CSC markers, many studies have identified CSCs from human HCC tissues and HCC cell lines expressing the following stem cell markers - EpCAM+, CD90+, CD44+, CD133+, AFP+, OV6+, and ALDH1+ [25, 27, 29, 30]. These diverse surface markers on CSCs have been thought to be a result of heterogeneity of tumor microenvironment, and no single surface marker can define HCC CSCs exclusively [31]. In hepatocellular carcinoma, studies have identified EpCAM+ cells in tumors of patients, and showed that these EpCAM+ cells correlate with

worse prognosis and possess CSC-like properties which showed tumor initiating capabilities in as few as 200 cells in a nude mouse model [18, 30, 32-34].

Recurrence of HCC after definitive tumor treatment occurs in over 70% of patients within 14 months of initial treatment. Clinical studies have shown that recurrent HCC tumors exhibit resistance to chemotherapy treatments and attain aggressive tumor growth [27]. CSCs are resistant to chemotherapeutics and considered as the primary players for tumor relapse and metastasis in HCC [35-37]. Importantly, multi-drug resistant transporter ABCG2, a well characterized CSC functional marker, has been implicated for doxorubicin resistance in multiple studies [28, 38-41]. Many recurrent HCC cases have a different biology than the primary index tumor. These recurrent tumors account for most therapeutic failures and eventually result in the death of patients. Molecular mechanism underlying chemotherapy resistance and tumor recurrence in HCC is not yet clear.

Wnt/ β -catenin Signaling, CSCs, and HCC:

Canonical Wnt/ β -catenin signaling pathway regulates several cellular events including cell proliferation, and is considered as a fundamental pathway in stem cell biology [42]. It is one of the most extensively studied molecular signaling pathways in HCC and CSCs [42]. In the

Nature. 2005 Apr 14;434(7035):843-50.

absence of Wnt ligand, β -catenin is in a complex with APC, Axin, and GSK-3 β (termed degradation complex), and gets phosphorylated and targeted for ubiquitin mediated degradation. β -catenin also exists in a cadherin-bound form and regulates cell–cell adhesion. When Wnt binds to frizzled receptor (Fz) and a member of LDL receptor family Lrp5/6 on cell membrane, GSK-3 β (non-phosphorylated, active state) gets phosphorylated at Ser-9 position (inactive state). β -catenin is uncoupled and gets stabilized following inactivation of GSK-3 β , and the stabilized β -catenin translocates into the nucleus, where it activates target genes by binding to TCF/LET transcription factors.

Many reports have demonstrated role of Wnt/ β -catenin signaling in tumorigenic CSCs [42]. EpCAM, one of the important CSC markers, is a target of Wnt/ β -catenin signaling and inhibiting Wnt/ β -catenin signaling has been shown to destroy EpCAM-positive cells [34, 36]. Studies have reported role of Wnt/ β -catenin signaling in self-renewal and maintenance of CSCs in HCC [43, 44]. Also, ABCG2, a functional CSC marker, was suggested to be regulated by β -catenin in CSCs and contributes to drug resistance [39, 40, 45].

Research Direction and Significance of Our Study:

Published studies have shown increasing evidence that support the role of CSCs in HCC carcinogenesis, chemotherapy resistance and tumor recurrence, and there is a compelling need to connect and better define these dispersed findings. Importantly, well-reported CSC surface marker EpCAM and CSC functional marker ABCG2 have been reported as targets of Wnt/ β -catenin

signaling, and also have been implicated in developing chemotherapy resistance and HCC prognosis. **However, origin and activation of CSCs in HCC is not yet been well defined.** Our primary goal is to understand the role of Wnt/ β -catenin pathway in HCC CSC activation and development of chemotherapy resistance. In pursuit of this goal, our first task was to enrich, identify and characterize CSCs in our laboratory setting.

In the present thesis work, we have successfully identified HCC cells with CSC-like properties in hepatoma cell lines using *in vitro* spheroid culture. These CSCs are poorly differentiated, and possess all defined CSC properties i.e. self-renewal, proliferation, and chemotherapy resistance. Surface markers analysis (EpCAM, CD90, CD44, and CD133) and functional markers analysis (ALDH and Hoechst efflux assays) further confirmed enrichment of CSCs, especially EpCAM+ CSC cells. Preliminary *in vivo* data in the mouse models support that spheroid forming CSCs show significant higher tumor proliferation rate compared to untreated (non-spheroid forming) HCC cells. Analyzing Wnt/ β -catenin pathway components in CSCs showed up-regulation of β -catenin expression, which is most likely a result of changes in GSK-3 β phosphorylation. Analysis of 24 paired human HCC specimens showed higher EpCAM expression compared to adjacent benign tissue.

CHAPTER II

MATERIALS AND METHODS

Cell Lines and Animal Models:

We have primarily used a mouse hepatoma cell line Hepa1-6 (ATCC CRL-1830) for all *in vitro* experiments. Hepa1-6 cell line is derivative of the BW7756 mouse hepatoma that arose in a C57L mouse. Hepa1-6 cells bear tumor initiating capabilities in an immune competent C57LJ mouse, in orthotopic as well as hind limb models. Use of Hepa1-6 cells with C57LJ mouse equipped us to establish the best HCC orthotopic model possible resembling clinical HCC closely in our lab.

We confirmed our findings in human hepatoma cell lines, Hep3B (ATCC HB-8064) and HepG2 (ATCC HB-8065). Our lab has an established HCC orthotopic animal model using Hep3B cells in BLAB/C nude mice.

Cell Culture and Spheroid Formation:

Hepa1-6 and Hep3B cells were grown in DMEM (MediaTech, Corning, Cat # 10-013-CV) with 4.5% Glucose, supplemented with 10% FBS (Sigma, Cat # F2442), 100 IU/mL Penicillin, 100 µg/mL Streptomycin, 0.25 µg/mL Amphotericin

(Antibiotic and Antimycotic, MediaTech Corning, Cat # 30-004-CI), 10 µg/mL Tylosin (Antimycotic, Sigma, Cat # T3397). HepG2 cells were grown in Minimum Essential Media (MEM, Gibco, Cat # 11095-080), supplemented with 10% FBS (Sigma, Cat # F2442), Non Essential Amino Acids (Gibco, Cat # 11140-050), Sodium Pyruvate (Gibco, Cat # 11360-070), 100 IU/mL Penicillin, 100 µg/mL Streptomycin, 0.25 µg/mL Amphotericin (Antibiotic and Antimycotic, MediaTech Corning, Cat # 30-004-CI), 10 µg/mL Tylosin (Antimycotic, Sigma, Cat # T3397).

For *in vitro* enrichment of Cancer Stem Cells (CSCs), we employed a widely used and accepted spheroid formation assay. Hepa1-6, HepG2, and Hep3B cells were grown in a serum-free condition (SF Group) in DMEM/F12 (1:1) media (SIGMA, Cat # D6434), supplemented with 2 mM L-Glutamine (SIGMA, Cat # G7513), 20 ng/mL recombinant human Epidermal Growth Factor (EGF, Sigma, Cat # E9644), and 10 ng/mL recombinant human basic Fibroblast Growth Factor (bFGF, Sigma, Cat # F0291), 100 IU/mL Penicillin, 100 µg/mL Streptomycin, 0.25 µg/mL Amphotericin (Antibiotic and Antimycotic, MediaTech Corning, Cat # 30-004-CI), 10 µg/mL Tylosin (Antimycotic, Sigma, Cat # T3397).

Self-Renewal Assay:

Hepa1-6 cells were seeded in serum-free (SF) media at a density of 2000 cells/well in 6-well plate, and incubated for 4 days to allow the development of spheroids. After confirming formation of spheroids under the microscope, these spheroid population of cells were collected in 15 mL centrifuge tube, treated with trypsin-EDTA for 4 minutes, and prepared single-cell suspension with 500

cells/mL density with SF media. Seed single cell suspension at 2 uL/well in 96 well plate. Mark the wells with one or two cells. Add 150 uL SF media in each marked well and monitor for 20 days. Images were taken on a daily basis to track progress.

Cell Proliferation Assay:

Cell proliferation was measured using the MTT assay (3-(4,5-dimethylthiazol-2-yl)-2,5 diphenyltetrazolium bromide) in a 96 well format. Hepa1-6 cells were seeded in triplicates at a density of 3000 cells/well in complete media (control group) or serum-free media (SF group) and grown overnight. A separate plate was prepared for each time-point (0, 24, 48, 72, and 96 hours). After appropriate incubation period, MTT was added in each well at the final concentration of 0.5 mg/mL, and plate was incubated for 3 hours at 37 °C in CO₂ incubator. After MTT incubation, media was removed from each well and 100 uL DMSO was added to dissolve formazon crystals which generate violet color. Absorbance was measured with plate reader at 540 nm with appropriate controls in each plate. For purpose of calculation, we considered the shorter incubation time MTT reading (overnight) as 0 hour and set it as control for the subsequent time points.

Doxorubicin (Adriamycin) Resistance Assay:

Hepatoma cells (Hepa1-6, HepG2, and Hep3B) were seeded at a density of 5000 cells/well in a 96 well plate in triplicates, with one set of control group (complete media) and two sets of spheroids group (serum-free media). Separate

96 well plates were seeded for different time points (24, 48, 72 and 96 hours) simultaneously on the day of seeding. After 24 hours, serum-free media is replaced with complete media in one of the two sets of spheroids group (termed as SFR, reserum) and incubated for another 24 hours. On the day 3, media is replaced with complete or serum-free media containing different concentrations of Doxorubicin (0.05 μ M, 0.5 μ M (clinical), and 5 μ M (10x clinical)) (SIGMA, Cat # D1515). MTT assay was performed at 24, 48, 72, and 96 hours after initiating DOX treatments as described in the cell proliferation assay. Each plate and group had appropriate untreated control in triplicates, and corresponding data for untreated group was considered as 1 i.e. 100 % viability. DOX treated cells were normalized to their corresponding untreated controls on the same plate, compared and analyzed.

Flow-Cytometry Analysis:

Hepa1-6 control or 7 day spheroid cells grown in 100 mm discs were collected by gentle cell scraping. Collected cells were passed through 50 micron strainer 5 times to remove cell clumps, followed by repeated pipetting for 10-20 times to obtain closest single cell suspension. Use of trypsin was avoided to preserve integrity of surface receptors to its best. Cell numbers were counted and single cell suspension was verified using a Hemocytometer. Each sample was transferred to a 15 mL tube and centrifuged for 5 minutes at 300 RCF to obtain cell pellet. Cell pellets were washed 2 times with 2% BSA/PBS. Pellets were resuspended in 100 μ L 2% BSA/PBS and transferred into 1.5 mL microfuge tubes. Corresponding unstained and single stained controls were separated for

each sample, 10^6 cells/100 μ L. FITC, APC or PE conjugated primary antibodies were added in 100 μ L of cell suspension as per datasheet or in-house optimized dilution (1:100 for most experiments and antibodies). Samples are gently vortexed and incubated in the dark at 4 °C for 1 hour. After incubation, cells were washed once with 1 mL 2%BSA/PBS, resuspended in 500 μ L 2% BSA/PBS, transferred into labeled flow-tubes, and stored in the dark on ice until analysis were performed. Data were recorded on BD FACSCanto. For analysis, after correct set-up of voltages for FSC and SSC, live cells were gated to exclude dead cells and cell debris. Required compensations were performed for dual FITC and PE staining experiments. In majority of our experiments, we chose FITC and APC (emission spectra don't overlap). Data analysis was performed either by FACS Diva or FlowJo software suites.

Immunocytochemistry (ICC) Staining:

Hepa1-6 control or spheroid cells were grown in 8 well Nunc™ Lab-Tek-II chamber slide (Thermo scientific, Cat # 154534) for 7 days (seeded at 100 cells/well to avoid overgrowth at the end of 7 days). Media was changed on the 4th day to ensure viability. Cells were fixed with 4% PFA for 30 minutes (or 70% ethanol overnight). Fixed cells were washed 2 times for 15 minutes with PBS-T, and blocked with 10% BSA in PBS for 20 minutes. Blocked cells were washed again for 2 times for 15 minutes with PBS-T and incubated with 100 μ L primary FITC conjugated antibodies at room temperature for 2 hours (EpCAM, CD90, CD133, 1:100 dilution in 10% FBS in PBS-T). Following antibody incubation, cells were given 3 time 10 minute PBS-T washes and stained for nuclear staining

with DAPI (1:1000 dilution). After DAPI staining, cells were given 2 time 10 minute PBS-T washes. Plastic chambers were removed from each Lab-Tek slides as per manufacturer's instructions, using the tools provided and exposed glassslide surface with cells were sealed with coverslip using 5-10% glycerin. The slides were examined using Olympus 1×51 microscope at 20x magnification using the Olympus DP72 digital camera via the cellSens Dimention imaging system (Olympus, Pittsburgh, PA) with FITC, DAPI and brightfield settings. Digital images were taken, stored and then overlapped using software tool to analyzed for FITC positive cells in each experiments.

Aldefluor Assay for ALDH Activity:

Aldefluor activity was assayed in Hepa1-6 control and spheroid cells using Aldefluor kit according to the manufacturer's instructions (Stemcell technologies, Canada). Briefly, 3 mL of cell suspension was prepared in DMEM without serum at 10^6 cells/mL final dilution. These cells were centrifuged at 250 RCF for 5 minutes, and pelleted cells were resuspended in 3 mL of Aldefluor buffer on ice. To get the fluorescence product, we added 45 uL of Aldefluore substrate into 3 mL of the each of the cell suspension samples on ice. Immediately after mixing, 1 mL was transferred into a new tube containing 30 uL ALDH1 inhibitor diethylaminobenzaldehyde (DEAB), and later used as an inhibitor control (negative control). Test samples and negative controls were incubated at 37 °C for 45 minutes, mixed every 10 minutes. Then, cells were cennrifuged at 250 RCF for 5 minutes, resuspended in Aldefluore buffer and incubated on ice for 1 hour.

Data were recorded on BD FACSCanto at FITC channel with 488 excitation laser.

Hoechst 33342 Efflux Assay:

After 7 days in culture, Hepa1-6 Control or spheroid cells were harvested in 15 mL centrifuge tubes. 5 mL cell suspension with 10^6 cells/mL was prepared for each sample, centrifuged at 250 RCF for 5 minutes, washed two times and resuspended in 2%FBS in PBS. Hoechst 33342 (Life technologies, Cat # H1399) dye was added to 5 mg/mL final concentration in 2% FBS in PBS and cells were incubated for 90 minutes at 37 °C. Cells were then incubated on ice for 10 minutes, and followed by a single wash of ice cold 1X PBS. These cells were immediately mounted on glass slides and analyzed within 1 hour on a fluorescence microscope with UV excitation settings. It is imperative that cells were viable during the steps of the assay. Hoechst 33342 dye stains the nuclear compartment and is visible at 355 nm excitation (blue color) using the common DAPI filter. Cells with dye exclusion property were identified by comparing/overlapping with images obtained under brightfield settings.

Protein Extraction and Western Blot:

After treating cells with respective media and/or regulators for desired time, media was aspirated from the culture and cells were washed two times with 1X PBS. Cells were lysed by adding SDS lysis buffer (supplemented with protease and phosphatase inhibitors, Thermo scientific, Cat # 78443) directly into wells (100 uL per well of 6-well plate or 500 uL per 100 mm plate). For spheroids

group (non-adherent cells), cells were collected by gentle scraping and pipetted into 15 mL centrifuge tube. Culture media was removed by centrifugation for 5 mins at 150 RCF to collect cells followed by two time 1x PBS washes to remove all media traces. Lysis buffer was then added into the tube according to pelleted packed cell volume (100 uL lysis buffer for each 20 uL packed cell volume). Cells were transferred to 1.5 mL microfuge tube and sonicated for 10-15 seconds on ice. After 30 minutes incubation on ice, lysates were centrifuged for 30 minutes at 14,000 RCF at 4 °C. Supernatant containing total cellular protein was collected carefully and transferred to new labeled 1.5 mL microfuge tube. Purified protein samples were stored at -80 °C until further use. For cytoplasmic and nuclear fractionation, we used a commercially available kit (Pierce, ThermoFisher, Cat # 78833). Fractionation was performed as per manufacturer's protocol. Extracted protein were stored at -80 °C until further use.

Extracted protein was quantified using the Bradford assay (Biorad, Cat # 500-0006) in a 96 well plate format and readings were performed at 620 nm using the ELISA reader (MultiSKAN MCC/340, Thermo Scientific).

Equal protein (20-50 µg each) were loaded for SDS-PAGE electrophoresis on 8% gel. Protein samples were separated by SDS-PAGE and then electrotransferred onto nitrocellulose membrane (Amersham, GE) . Following electrotransfer, the membrane was blocked in 5% non-fat milk for 1 hour at room temperature. The membrane were incubated in primary antibody overnight at their best working concentration (1:1000 or 1:2000 final dilution). Next day, the membrane with overnight incubated primary antibodies were washed 3 times

with TBST for 7 minutes each. Next, the membrane was incubated for 1 hour in secondary HRP conjugated-Anti-Mouse IgG (Cell Signaling, Cat # 7076; OR Santacruz Biotech, Cat # sc-2005) or secondary HRP conjugated-Anti-Rabbit IgG (Cell Signaling, Cat # 7074; OR Santacruz Biotech, Cat # sc-2004).

Secondary antibodies were diluted either 1:2000 or 1:4000 as per experimental requirement. Secondary antibody blot was washed 3 times by TBST, followed by 1 wash of TBS and incubated in dark for 1 minute in Western Blot Luminol Reagent (Santacruz Biotech, Cat # sc-2048). Chemiluminescence signals were detected in the darkroom using x-ray films. Densitometry analysis were conducted using ImageJ software (NIH).

Primary antibodies: β -Catenin (SantaCruz Biotech, Cat # sc-7963), β -actin (SantaCruz Biotech, Cat # sc-81178) , GAPDH (SantaCruz Biotech, Cat # sc-365062), GSK3 β (Cell Signaling, Cat # 9832), phospho-GSK3 β (Ser-9) (Cell Signaling, Cat # 5558), ABCG2 (Cell Signaling, Cat # 4477), Cyclin-D1 (Cell Signalling, Cat # 2978), TCF-1 (Cell Signaling, Cat # 2203), C-MYC (Cell Signaling, Cat # 5605).

Animal Experiments:

All experimental procedures were approved by the Institutional Animal Care and Use Committee (IACUC) at University of Louisville (UofL). IACUC at UofL is certified by American Association for Accreditation of Laboratory Animal Care. All mice were housed in the University of Louisville Research Resources Center at 22 °C with 12-h light/dark cycle with free access to food and water.

In vivo experiments using Hepa1-6 cell-lines were performed in 8 week old C57L/J mice (All male). Each group had 3 animals. For orthotopic inoculation, 1×10^7 Hepa1-6 control or spheroid forming cells (serum free group – 7 day treatment), were injected into liver of the animal. Post injection, mice were monitored for two weeks and then euthanized. Animal weight, liver weight, tumor weight, and tumor size were recorded for each animal. *In vivo* study using human Hep3B cells was performed in the same way in 8 week old orthotopic BLAB/C nude mouse model.

Human HCC Specimens:

This study was approved by the Institutional Review Board for Human Study at University of Louisville. The study samples were retrospectively collected from 24 patients who had undergone liver resection for hepatocellular carcinoma between 2002 and 2013. 24 subjects, 13 male (54.2%) and 11 female (45.8%) with a median age of 67, ranging from 41 to 84 years old, had a clinical diagnosis of hepatocellular carcinoma and underwent liver resection. The control samples consisted of the same 24 patients' normal adjacent tissue that were within the resected liver specimen.

Immunohistochemical Assay for EpCAM in Human Specimens:

EpCAM protein expression were determined by using an immunohistochemical assay. Staining was carried out on the paraffin-embedded tissues using the DAKO EnVision™+System kit (DAKO Corporation, Carpinteria, CA) according to the manufacturer's instructions. The sections were

deparaffinized and hydrated, then the slides were washed with TRIS buffer. Peroxidase blocking was performed for 5 minutes. After rewashing, the slides were incubated with EpCAM antibody (1:100) (SantaCruz Biotechnology Inc, CA) for 30 minutes at room temperature. The slides were rinsed and the specimens were incubated with the labeled polymer for 30 minutes at room temperature. Then, the chromogenic substrate diaminobenzidine was added as a visualization reagent. Finally, the slides were counterstained with methyl green for EpCAM. A negative control was included in each run.

Computer Image Analysis of IHC:

A computer image analysis was performed to quantify the expression of EpCAM in the 24 samples diagnosed with HCC, and in the 24 samples of adjacent normal liver (AD). The imaging fields were chosen randomly from various section levels to ensure objectivity of sampling. Five imaging fields were scanned for each specimen sample. All digital images were acquired with the Olympus i×51 microscope at 40x magnification using the Olympus DP72 digital camera via the cellSens Dimension imaging system (Olympus, Pittsburgh, PA) and stored as JPG data files with fixed resolutions of 200 pixels/inch. The acquired color images from the immunohistochemical staining were defined at a standard threshold according to the software specification. The computer program then quantified the threshold area represented by color images. EpCAM protein expression was defined by the percentages of threshold area in acquired color images.

Statistical Analysis:

Data are presented as mean $\pm$ S.D. ($n \geq 3$ per group). Comparisons were performed by two-tail student's t-test with equal variance (Microsoft Excel 2013). For analysis of human specimens, analysis of variance (ANOVA) was used to determine the differences in EpCAM expression between paired samples. Results with $p \leq 0.05$ were considered statistical significant.

CHAPTER III

RESULTS

Hepatoma Cells Could Form Anchorage-Independent, Self-Renewing Spheroids (Spheres) in Serum-Free Culture *in vitro*:

Serum-free conditions enriched in growth factors allow cells to grow in anchorage-independent manner, and is a well-documented and standard method for maintaining undifferentiated cells [46]. This technique is widely adapted for CSC studies in breast cancer [47] and glioblastoma [48]. Soon after, this technique was accepted and used in many other solid tumor malignancies including hepatocellular carcinoma [27, 49]. Also known as spheroid formation (sphere formation) culture, this is not only a CSC property, but also serves as a valuable tool to enrich CSC-like cells *in vitro*.

To enrich HCC CSCs from hepatoma cell lines *in vitro*, we employed serum-free conditions using DMEM/F-12 (1:1) media supplemented with recombinant human Epidermal Growth Factor (EGF) and basic Fibroblast Growth Factor (bFGF). We evaluated spheroids for CSC properties. We found that all three hepatoma cell lines (Hepa1-6, HepG2, Hep3B) successfully formed spheroids in serum-free conditions (Figure-1).

Self-renewal capability is the most fundamental property of CSCs and proposed as the primary mechanism responsible for maintaining undifferentiated cells with CSC like properties in tumors [50]. We have primarily characterized Hepa1-6 spheroids. To test if enriched Hepa1-6 spheroids possess self-renewal capability, we performed two separate experiments. In the first experiment, we tested if spheroid cells can be serially passed from one generation to the next without dying or losing spheroid forming capability. The rationale behind this experiment is that well differentiated cells cannot survive in serum-free stress conditions optimized for anchorage independent growth, while only cells with stem-like properties are able to maintain themselves and propagate. Hepa1-6 spheroids were serially passaged for more than 10 generations in serum-free conditions, indicating their self-renewal capability (data not shown).

In the second experiment, we confirmed self-renewal capability of CSC like cells by means of more quantitative “self-renewal assay”. Hepa1-6 spheroid cells were seeded in 96 well plates (single cell/well) and monitored for their growth pattern daily for 20 days (Figure-2). In this condition, cells can have one of the three fates: 1) self-renewal (spheroid formation), 2) differentiation (adherent phenotype), 3) quiescence (stays as a single cell). Approximately, 24% Hepa1-6 cells showed self-renewal capability by forming spheroids. These growing spheroids (Figure-2.A & C) also expressed EpCAM (CSC marker), further supporting CSC like-properties of spheroids. Around 51% cells stayed in the quiescence state, while about 25% cells lost their stem-ness and proceeded to differentiation (Figure-2.D).

We also performed an MTT assay to quantitate cell proliferation rates in Hepa1-6 control and spheroid cells. We have found that Hepa1-6 spheroids retained proliferative capability but growth rate is significantly slower than parental control cells (Figure-3).

Figure 1. Representative Images of Cultured Cells. Bright field microscope images. **(A)** Control hepatoma cells and **(B)** CSC Spheroids (Serum-free /SF group) in Hepa1-6, HepG2, and Hep3B cell lines. 4x (Bar = 500 μ m), 10x (Bar = 200 μ m), and 20x (Bar = 100 μ m).

Figure 2. Hepa1-6 CSC Spheroids Possess Self-Renewal Capability in Serum-Free Condition. Hepa1-6 cells were seeded in 96 well plate with appropriate dilution to achieve single cell/well, and observed for two weeks. **(A)** Bright field microscope images at different time-points. **(B)** DAPI and FITC-EpCAM (CSC marker) staining, **(C)** Graph showing sphere growth with time, **(D)** Quantified cells for self-renewal (spheroid formation), differentiation (adherent growth), and single cell (Quiescent cells). 10x (Bar = 200 μ m).

Figure 3. Hepa1-6 Spheroids Retained Proliferative Capability. MTT Assay was performed in 96 well plate, with seeding 3000 cells/well in triplicates. CSC spheroids retained proliferative capabilities in serum-free media, but exhibit slower growth rate compared to control group cells (complete media with serum). n= 3 independent experiments. Values shown in "Mean ± S.D".

HCC Spheroids Possessed Resistance Ability to Chemotherapy Drug

Doxorubicin:

Resistance to chemotherapeutics is another important characteristic of CSCs, and is believed to play a significant role in HCC carcinogenesis and recurrence [24]. Currently, doxorubicin (Adriamycin, DOX) is a first line drug used for HCC treatment in clinics [2].

We studied Hepa1-6 spheroids for their DOX resistance property with MTT assay as described in materials and methods. For *in vitro* experiments, we selected a clinical relevant dose (0.5 μ M) as characterized in early pharmacokinetic studies in patients and widely employed by other groups for DOX studies [51]. We have also tested 1/10 (0.1x, 0.05 μ M) and 10 times (10x, 5 μ M) doses for characterization. Time dependent dose response curves have demonstrated that Hepa1-6 CSC spheroids were sensitive to DOX at early time points, but developed resistance 48 hours post DOX treatment at both subclinical and clinical doses (Figure-4). We found that for the 10x dose, 5 μ M, there were a fraction of cells that retained higher viability after 72 hours.

When we further analyzed our data by plotting log (DOX dose) v/s viability at 96 hour time-point, we found that Hepa1-6 spheroids required 2 times more DOX compared to control cells to eradicate 50% viable cells (Figure-5.A). Hepa1-6 spheroids were seen to have significantly increased chemotherapy resistance for doxorubicin at not only physiologically relevant dose of 0.5 μ M but also to 10 fold dose increase (5 μ M) ($p < 0.005$) (Figure-5.B).

We have also investigated HepG2 and Hep3B spheroids for their DOX resistance properties. After 96 hours of treatment, both HepG2 and Hep3B CSC spheroids showed significant higher resistance for DOX compared to control cells at clinical dose of 0.5 μ M ($p < 0.05$) (Figure-6). These data support our results found in Hepa1-6 spheroids.

Figure 4. Hepa1-6 Spheroids Exhibit Chemotherapy Resistance for Doxorubicin (DOX) in Serum-Free Condition. Hepa1-6 cells were seeded in triplicates in 96 well plate at 3000 cells/well, and studied for their chemotherapy resistance property by MTT assay. Media changed with DOX media (Media + Doxorubicin) after 48 hours of seeding for C and SF groups. For SFR group, 1 day serum-free treatment followed by 1 day re-serum, before changing to DOX media. Value 1 on y-axis represents 100% cell viability. **(A)** DOX treatment at 0.05 μM (subclinical dose). **(B)** DOX treatment at 0.5 μM (Clinical dose). **(C)** DOX treatment at 5 μM (10 times higher than clinical). **C** = Control Group, **SF** = Serum-free Group, **SFR** = Re-serum Group. Enriched HCC Spheroids Showed Higher Expressions of Cancer Stem Cells (CSCs) Surface Markers and Functional Markers:

Surface and functional markers are currently the best available tools to define the origin and lineage of cells in animal tissues, and therefore, these tools are extensively employed to characterize CSCs in solid malignancies including HCC [11, 31, 52]. Most extensively characterized and reported surface markers for HCC CSCs are EpCAM, CD90, CD44, AFP, OV6, and CD133 [27, 31, 53]. It is noteworthy that EpCAM⁺ and CD90⁺ cells are physiologically different in terms of their tumorigenic potential and differentiation stage [34], and so is true for other markers. Because of a high degree of heterogeneity, no single marker could confidently and exclusively define HCC CSCs. Extensive research is being done globally in this pursuit.

In order to confirm CSC-like properties in HCC spheroids, we selected extensively reported and studied surface markers i.e. EpCAM, CD90, CD44, and CD133, and tested HCC spheroids for their expression by flow-cytometry and ICC. Our findings suggest that HCC spheroids showed up-regulation in EpCAM levels compared to control, and EpCAM⁺ cells are enriched in spheroid culture (Figure-7.A). We confirmed our findings with ICC using anti-EpCAM antibodies (Figure-7.B). We have also confirmed up-regulation of CD90, CD44, and CD133 in spheroid culture with enrichment of CD90⁺, CD44⁺, CD90⁺/CD44⁺, and CD133⁺ cells (Figure-8). Each of these subpopulations bears different physiological properties and differentiation states e.g. CD44⁺/CD90⁺ cells were suggested as more tumorigenic and less differentiated compared to

CD44+/CD90- or CD44-/CD90+ cells alone [31]. Our findings confirmed that *in vitro* Hepa1-6 spheroids can enrich all important CSC subpopulations reported so far.

As it is defined by its asymmetric cell division property and hierarchical importance, the CSC theory is a functional concept. Two extensively reported functional markers to define CSCs, ALDH activity and Hoechst 33342 efflux assays [28, 54], were also tested in Hepa1-6 CSC spheroids. Hepa1-6 spheroids showed 1.3% increase in ALDH+ cells (Figure-9.A). Also spheroid cells have showed property of dye exclusion (Figure-9.B), which was confirmed by Western Blot analysis of ABCG2, multi-drug resistant transporter responsible for dye exclusion (Figure-9.C). Dye efflux depends on expression and activity of ABCG2, and clinically correlates with drug resistance including doxorubicin [28].

Figure 7. Hepa1-6 Spheroids Showed Increased EpCAM Expression. Hepa1-6 cells were grown in serum-free media (spheroids) or control media for 7 days. After 7 day treatment, cells were harvested and analyzed for EpCAM expression. **(A)** EpCAM expression analysis by flow-cytometry using APC conjugated Anti-EpCAM antibodies, ******($p < 0.005$), $n = 4$ independent experiments, **(B)** EpCAM expression analysis by ICC using FITC conjugated Anti-EpCAM antibodies. 7 Day SF treatment. Cells were fixed, stained and analyzed by fluorescence microscopy at 20x magnification (Bar = 100 μ m). DAPI stains nuclei.

Figure 8. Hepa1-6 Spheroids also Showed Increased CD44, CD90 and CD133 Expression, Well Reported CSC Surface Markers. Hepa1-6 cells were grown in serum-free media (spheroids) or control media for 7 days. Hoechst 33342 stains nuclei. **(C)** Representative Western Blot and densitometry analysis of ABCG2 expression. Increased ABCG2 expression in spheroids compared to control. $^*(p < 0.05)$, $n = 3$ independent experiments. **C**=Control; **SF**=Serum-free.

Up-Regulation of β -catenin in HCC CSC Spheroids:

Many signaling pathways are implicated and studied in CSCs [55]. Wnt/ β -catenin pathway is the cardinal pathway in normal stem cell maintenance and highly implicated in HCC and CSCs [42, 56].

Enriched Hepa1-6 CSCs showed increased β -catenin protein levels both in the cytoplasm (1.53 ± 0.21 fold, $P < 0.05$) as well as in nucleus (1.54 ± 0.15 fold, $p < 0.001$) compared to control cells (Figure-10). We have also tested β -catenin levels in HepG2 cells and found it to be consistent with our findings in Hepa1-6 cells (data not shown, downstream target studies were not completed in HepG2 cells when this thesis was being written).

To further confirm functional consequences of higher β -catenin levels in Hepa1-6 CSC spheroids, β -catenin downstream targets (C-MYC, Cyclin-D1, LEF1) were analyzed by Western Blot analysis. All three downstream targets we tested were proportionately increased with increased β -catenin levels (Figure-11), suggesting that higher β -catenin levels in CSC spheroids have functional consequences. More importantly, C-MYC and Cyclin-D1 are highly implicated in carcinogenesis [12].

To further investigate the increase in β -catenin levels, we tested GSK-3 β phosphorylation status. Active GSK-3 β (no Ser9 phosphorylation) directs cytoplasmic β -catenin to ubiquitin mediated proteasomal degradation by phosphorylating β -catenin at S33/S37/T41 positions. However, when GSK-3 β itself is phosphorylated at Ser9 position, it loses its substrate specificity for β -

catenin and cytoplasmic β -catenin gets stabilized, translocates to the nucleus and regulates transcription at the gene level. Hepa1-6 CSC spheroids showed increase in inactive GSK-3 β levels (phosphorylated at Ser9) compared to control cells (Figure-12). This finding suggests that GSK-3 β activity at least partially contributed to increased β -catenin levels in Hepa1-6 spheroids and needs to be investigated further.

Figure 10. Hepa1-6 Spheroids Showed Increased β -catenin Levels. Hepa1-6 cells were grown for 7 days in serum-free media (SF) or complete media (control). Cells were harvested after 7 day treatment, and cytoplasmic and nuclear proteins were extracted. **(A)** Representative Western Blot. **(B)** Densitometry image analysis. * ($p \leq 0.05$), ** ($p \leq 0.005$), $n=3$ independent experiments. β -actin used as loading control. **Cyto** = Cytoplasm; **Nuc** = Nuclear; **C**=Control; **SF**=Serum-free.

No change was observed in total GSK-3 β levels, but phosphorylated GSK-3 β (Ser9) levels were increased in CSC spheroids compared to control. **(A)** Representative Western Blot, **(B)** Densitometry image analysis. ******($p \leq 0.005$), $n=3$ independent experiments. β -actin used as loading control. **C**=Control; **SF**=Serum-free.

HCC CSC Spheroids Possess Higher Tumorigenic Capability *in vivo*:

CSCs have been suggested to possess increased tumorigenic properties *in vivo*. To test tumorigenic potential of Hepa1-6 spheroids, we used an orthotopic C57LJ mouse model. We injected seven days cultured 1×10^7 Hepa1-6 spheroids and non-spheroid control cells into livers of 8 week old immunocompetent C57LJ mice (n=3 mice in each group) and monitored for two weeks. Mice injected with Hepa1-6 spheroids developed more aggressive tumors with overall higher tumor volume (5800 mm^3) compared to mice injected with non-spheroid cells (1900 mm^3) (Figure-13.A). Aggressive nature of CSC tumors was also witnessed at multiple sites within the liver compared to control, suggesting that CSC spheroids possess increased tumor initiation capabilities (Figure-13.A). Increased liver weight was observed in spheroid group (3.9 ± 1.6) compared to control group (1.7 ± 0.43), which is likely due to aggressive growth and higher tumor mass in spheroids injected group. This justifies the increased overall body weight by about 2.3 gms in spheroids group compared to control. We were unable to perform statistical tests for significance because one Hepa1-6 spheroids injected mouse died within 2 weeks of injection due to extremely aggressive tumor growth.

We also studied Hep3B spheroids in orthotopic BALB/C nude mouse model. Hep3B spheroids also supported our findings in Hepa1-6 and showed aggressive tumor growths in the spheroid group compared to non-spheroid group (Figure-13.B). EpCAM is extensively reported CSC marker in HCC, and also found to be higher in our Hepa1-6 spheroids. We studied EpCAM expression by

Western Blot in Hep3B xenograft tissues, and found EpCAM up-regulation in the spheroid group compared to the non-spheroid group (Figure-13.C).

Figure 13. CSC Spheroids Possessed Higher Tumorigenic Capability. Tumors in spheroid group animals were more aggressive and proliferative compared to control. **(A)** Upper-Orthotopic C57LJ mice with 1×10^7 CSC spheroids or control Hepa1-6 cells injected into liver of each animal (n=3 animals in each group). Lower- quantified tumor volumes. **(B)** Orthotopic BALB/C nude mice with 1×10^7 CSC spheroids or control Hep3B cells injected into liver of each animal (n=3 in each group). Tumor tissues of BALB/C xenograft were further studied for EpCAM expression. **(C)** Western Blot analysis of two Hep3B spheroid tumors and control tumor. EpCAM expression levels were found to be higher in the Hep3B spheroid group. **C:** Control group; **T1 & T2:** Hep3B spheroid tumors.

Analysis of Human Specimens Found Significant Higher EpCAM

Expressions in HCC Tissues:

Total protein was extracted from 8 pairs of malignant tissues and adjacent benign tissues. Western Blot analysis was performed to analyze the EpCAM and β -catenin expression in these tissues (Figure-14.A & B). Results showed that, in 4 paired tissues, EpCAM expression was higher in malignant tissue compared to the benign adjacent tissue (samples 1, 2, 5, and 6). In 3 paired tissues, EpCAM expression was only slightly increased in malignant tissue compared to the benign adjacent tissue (samples 3, 4, and 8). However, in one pair (sample 7), EpCAM expression remained unchanged. β -catenin expression levels were found to be high in 5 paired samples (samples 1, 2, 4, 5, and 6). However, in pair 3, pair 7 and pair 8, β -catenin expression levels were found to be lower in malignant tissue compared to benign adjacent tissue.

We have also examined 24 pairs of HCC tissues and adjacent benign control by IHC (Figure-14.C). Our data showed significant increase in EpCAM expression in specimens with HCC (483.75 ± 119.92 , $p < 0.0001$) when compared with the normal liver tissue within the resected specimens (38.44 ± 7.31).

Figure 14. Analysis of Human Specimens. Total proteins were extracted from 8 pairs of human HCC specimens (tumor tissue and adjacent benign tissue) and analyzed SDS-PAGE followed by Western Blot for EpCAM and β -catenin expression. **(A)** Western blot; **(B)** densitometry image analysis of EpCAM (left) and β -catenin (right) expression in malignant tumor tissue and adjacent benign tissue (n=8). **T:** tumor tissue; **B:** benign adjacent tissue. CHAPTER IV

DISCUSSION

Recent studies have shown that many epithelial cancers including hepatocellular carcinoma (HCC) arise from small subpopulation of cells called cancer stem cells (CSCs) [10, 11, 57]. According to CSC theory, tumors are hierarchically organized with heterogeneous populations of cells where a few subpopulations called CSCs are poorly differentiated and functionally acquire the apex position in the hierarchy of differentiation [13]. These poorly differentiated CSCs are believed to be responsible for tumor growth and maintenance of tumor mass during carcinogenesis. CSCs acquire this apex role by acquiring self-renewal capability, where asymmetric divisions maintain CSC populations as well as contribute to tumor mass by differentiation [58]. Poorly differentiated CSCs also possess spheroid formation capabilities under serum-free conditions where most differentiated cells cannot survive. CSCs also possess chemoresistance property that results in up-regulation of drug resistant transporters [57, 59]. Much of the advanced knowledge on CSCs comes from the studies that have used FACS technology to isolate and enrich CSCs from primary HCC tumors, and then test their propagation in nude mice [18, 19, 34, 60]. This approach, although

proven the most valuable, is cumbersome, time-consuming, expensive, and do not readily enable either characterization of CSCs or their functional properties. Tumor heterogeneity in primary HCC and variation in HCC patients are key reasons for these limitations. In most laboratory conditions, primary tumor cells obtained from patient's HCC tissue, lose their original phenotype during first few passages in culture. In contrast, cell lines derived from hepatoma normally have homogeneous cells and lack heterogeneity observed in clinical tumors. Despite these limitations, cell lines can provide valuable tools to study drug development, characterization, and to investigate biochemical mechanisms.

Serum-free conditions enriched in growth factors allow cells to grow in an anchorage-independent manner, and is a well-documented standard method for maintaining undifferentiated cells [46, 61-63]. Spheroids formed in serum-free culture have been suggested to mimic not only phenotype but also genotype of the primary tumor than cells in normal culture media [48]. One study disagreed with this notion and showed that not all cell lines can enrich CSC-like cells in spheroid culture, and each cancer cell line should be evaluated subjectively [64]. On the other hand, more and more groups are now testing their hypothesis in spheroid culture. A recent study reported that simply generating multicellular spheres followed by reversal to adherent cell line can significantly change phenotype and can be used as *in vitro* metastatic model [61]. Altogether, spheroid cultures provide a balanced approach to enrich and study CSC-like cells present in primary tumors with added advantage of reproducibility and validity of findings.

In the present study, we successfully identified HCC cells with CSC-like properties (derived from hepatoma cell lines) using serum-free culture system. Enriched spheroid cells showed self-renewal capability, and serially passed for more than 10 generations in serum-free culture. HCC CSC spheroids showed resistance to chemotherapeutic drug Doxorubicin, with concomitant up-regulation of ABCG2 expression - a multi-drug resistant transporter responsible for efflux of drug from the cell [28]. We also studied putative HCC CSC markers by flow-cytometry and ICC. Our findings suggest that EpCAM⁺, CD90⁺, CD44⁺, and CD133⁺ CSC subpopulations were successfully enriched in spheroids compared to control group. We also studied reported functional markers (ALDH activity and Hoechst 33342 efflux) and confirmed functionally active CSC-like cells in spheroids. For final benchmark confirmation, we injected equal numbers of spheroids and control cells into established orthotopic mouse models (C57L/J for Hepa1-6, and BALB/C for Hep3B) and showed that enriched CSC spheroids possess high tumorigenic property contributing to aggressive tumor growth *in vivo* compared to control cells.

We have analyzed 24 pairs of human HCC specimens and confirmed significant up-regulation of EpCAM in HCC tissues compared to adjacent benign liver tissues. EpCAM is an extensively studied CSC marker in HCC, and EpCAM⁺ cells showed higher tumorigenicity and chemoresistance [18]. Yamashita et al. studied and suggested a novel HCC classification with prognostic implications based on EpCAM⁺/AFP⁺ cells in HCC where higher numbers of EpCAM⁺ HCC cells correlated with worse clinical prognosis [33]. A

study by Terris et al. suggested EpCAM as a potential Wnt/ β -catenin signaling target [32]. Our studies in human specimens in 8 pairs of HCC and adjacent benign tissues showed concomitant increase and decrease in EpCAM and β -catenin levels. Also, 5 out of 8 pairs showed increased expression in both EpCAM and β -catenin.

Accumulated evidence have been established that Wnt/ β -catenin pathway plays a vital role in not only normal stem-cell biology but also in HCC carcinogenesis. We found increased levels of β -catenin in HCC spheroids, both in the cytoplasm and the nuclei than in control cells. Also, β -catenin downstream gene targets (C-MYC, Cyclin-D1, LEF1) were also upregulated, further supporting functional consequences of higher β -catenin levels in CSC spheroids. Finally, we also found changes in GSK-3 β phosphorylation status where HCC CSC spheroids have higher levels of S9-phospho-GSK-3 β compared to control. This could be a possible mechanism for higher β -catenin levels and its downstream effect in HCC spheroids need to be investigated further.

Chemotherapy plays a significant role in decreasing mortality and improving the survival in HCC patients. However, chemoresistance whether acquired or inherent, greatly affects disease free survival and early HCC recurrence in patients. Mechanisms involved in anticancer chemotherapy are multifaceted and largely undefined in HCC. Since chemotherapy resistance is an important property of CSCs, characterizing CSCs and establishing an *in vitro* tool to study chemotherapy resistance is of great value in translational research. In our present study, enriched HCC spheroids showed phenotypic diversity and

significant doxorubicin resistance in all three hepatoma cell lines (Hep1-6, HepG2, and Hep3B). Also we demonstrated higher ABCG2 expressions in CSC spheroids compared to control. Recently, two drug resistance studies in breast cancer have identified functional role of β -catenin/ABCG2 signaling [39, 40]. Study by Chua et al. suggested ABCG2 as transcriptional target of Wnt/ β -catenin signaling [45]. All these studies together with our results strongly suggested Wnt/ β -catenin signaling pathway is implicated in HCC chemoresistance via HCC CSCs.

Summary and Future Directions:

Our work has successfully identified CSC-like properties in HCC spheroids. These CSC spheroids showed resistance to Doxorubicin, first line drug to treat HCC in clinics. 24 pairs of human specimens we analyzed have shown increased expression of EpCAM, well established HCC CSC marker. Expression of EpCAM and ABCG2, multi-drug resistant transporter, have been implicated in HCC patients and suggested to be under the regulation of Wnt/ β -catenin signaling. However, exact mechanisms are not clear at this point in time. We believe that the chemotherapy resistant properties of HCC tumors could be contributed by Wnt/ β -catenin signaling mediated CSC activation. For future work, we will study the role of Wnt/ β -catenin signaling in activation/origin of CSCs in HCC and findings will be used to establish clinical correlation(s) in HCC patients. Expected clinical correlation(s) with HCC prognosis and chemotherapy resistance could help in determining treatment modalities during primary tumor treatment and improve disease free survival in HCC patients.

CURRICULUM VITAE

Harshul Pandit, M.Sc.

779 Theodore Burnett Ct, Apt # 7

Louisville, Kentucky 40217

Ph: (502) 657-8783

harshul.pandit@louisville.edu

EDUCATION

- 2011-Present Ph.D. in Pharmacology & Toxicology, University of Louisville,
Louisville, KY, USA.
- 2005-2007 M.Sc. in Biochemistry (thesis), M.S.University of Baroda, Baroda, India.
- 2004-2005 PG. Diploma in Applied Biochemistry, M.S.University of Baroda, Baroda,
India.
- 2001-2004 B.Sc. in Biotechnology, Sardar Patel University, Vallabh Vidhyanagar,
India.

ACADEMIC APPOINTMENTS

- 2013-Present Graduate Research Assistant, Division of Surgical Oncology, Department
of Surgery, University of Louisville, Louisville, KY.
- 2012-2012 Graduate Teaching Assistant, Department of Biochemistry, University of
Louisville, Louisville, KY.
- 2010-2011 Instructor (Mathematics), PT Education Center, Bhuj, India.

EMPLOYMENT

- 2009-2010 Research Associate E-I, R&D Division, Protein purification - Down
Stream Process Lab, Intas Biopharmaceuticals Ltd, Ahmedabad, India.
- 2008-2009 Trainee Research Associate E-II, R&D Division, Protein purification -
Down Stream Process Lab, Intas Biopharmaceuticals Ltd, Ahmedabad,
India.

OTHER POSITIONS

- 2014-2015 Graduate Student Representative (Elected) for School of Medicine Faculty Forum, School of Medicine, University of Louisville, KY.
- 2013-Present Laboratory procurement, Surgical Oncology Lab, Department of Surgery, Louisville, KY.
- 2004-2007 Laboratory and Chemical In-charge, Department of Biochemistry, M.S.University of Baroda, Baroda, India.

HONORS AND AWARDS

- 2014 Conference Travel Award, HSC Research Office, University of Louisville, Louisville, Louisville, KY.
- 2014 Conference Travel Award, Graduate Student Council - SIGS, University of Louisville, Louisville, Louisville, KY..
- 2013 Antibody credits for buying research chemicals and antibodies, Cruz credit program, Santacruz Biotech, TX.
- 2011-2013 Interdisciplinary Program in Biomedical Sciences (IPIBS) fellowship, University of Louisville, Louisville, KY.
- 2009 Selected for 35th Mahabaleshwar Seminar at national level, organized by Tata Institute of Fundamental Research (TIFR) Mumbai, India.
- 2006-2007 Selected for 3rd Bangalore Benny Shilo course in Developmental Biology at International level, organized by Weizmann Institute, Israel & National Center for Biological Sciences (NCBS), Bangalore, India.
- 2003 Charutar Vidhya Mandal (CVM) award - “Scholar student in the college”, N.V.Patel College of Pure and Applied Sciences, Vallabh Vidhyanagar, India.
