A Dissertation Approved on

November 20th, 2018

By the following Dissertation Committee

Dr. Suresh C. Tyagi, Ph.D., Mentor

Dr. Barbara J. Clark, Ph.D.

Dr. Claudio Maldonado, Ph.D.

Dr. Marsha Cole, Ph.D.

Dr. Corey Watson, Ph.D.

DEDICATION

This dissertation is dedicated to my mother, Mrs. Kaberi Majumder, for supporting and encouraging me throughout my entire life.

ACKNOWLEDGEMENTS

I would like to thank my mentor, Dr. Suresh C. Tyagi for his continuous support and encouragement throughout my time in his laboratory. His mentorship and passion for scientific understanding are truly unsurpassed. I would also like to thank him for believing in me during my doctoral program, and it was a privilege to work and learn under his able guidance and constant supervision. I am grateful to Dr. Clark for serving in my Ph.D. thesis committee and for her support during my doctoral studies. I would like to thank Dr. Maldonado for providing valuable insight and advice throughout my research endeavors. I would like to thank Dr. Cole for serving on my committee and for elevating my personal understanding of biochemistry to new heights. I would like to thank Dr. Watson for serving on my committee and for all of his support and advice over the years. I also would like to extend my most sincere gratitude to all of the professors in the Biochemistry & Molecular Genetics Department and Departments of Physiology for their remarkable academic instruction. I would like to thank the administrative staff at the Department of Physiology as well as Biochemistry & Molecular Genetics for all of their assistance over the years.

I would like to thank all of the members of my lab for providing a supportive network, a collegial environment and years of friendship. Special thanks to Mrs. Naira Metreveli, Dr. Mahavir Singh, and Dr. Neetu Tyagi for their continuous assistance and advice during my time in the lab. I would like to extend a very special thanks to Dr. Sen for his assistance, guidance, and friendship that have been invaluable for my success as a doctoral student. He has my deepest gratitude.

I would like to thank all of my friends and family for their unwavering support.

Thanks to my sister, Mrs. Amrita Maji, for her support and encouragement over the years. Very special thanks to my mother, Mrs. Kaberi Majumder, and my father, Mr. Biswanath Majumder, for providing me the unwavering love and support in everything I do. I want to convey to them that they have been an inspiration to me throughout my life; thank you, my dear parents. Lastly, I would like to thank my incredible wife, Rani, for always supporting me during tough times and for making my life better in every way imaginable.

ABSTRACT

EFFECTS OF HYDROGEN SULFIDE IN HYPERHOMOCYSTEINEMIA-MEDIATED SKELETAL MUSCLE MYOPATHY

Avishek Majumder

November 20th, 2018

Although hyperhomocysteinemia (HHcy) occurs due to a deficiency in cystathionine- β -synthase (CBS), causing skeletal muscle myopathy, it is still unclear whether this effect is mediated through oxidative, endoplasmic reticulum (ER) stress, both or something else. Cystathionine γ -lyase (CSE) and CBS are the main H₂S producing enzymes, which produce Hydrogen sulfide (H₂S) from Hcy in the transsulfuration reaction. H₂S is an anti-oxidant compound and patients with a CBS deficiency cannot produce enough H₂S, thus rendering them vulnerable to excess Hcy-mediated damage.

Both *in-vitro* (C2C12 cells) and *in-vivo* (CBS^{+/-} mice) models were used to study HHcy-mediated muscle myopathy, and they were treated with sodium hydrogen sulfide (NaHS, an H₂S donor) to mitigate the effect(s) of HHcy in skeletal muscle. To examine whether muscle myopathy is due to poor angiogenesis, we created a hind limb femoral artery ligation (FAL) in CBS^{+/-} mouse model and treated them with GYY4137 (a long-acting H₂S donor compound).

Results showed that oxidative stress was reversed by NaHS (H₂S donor) in Hcy-treated C2C12 cells. ER stress markers (GRP78, ATF6, and pIRE1α) were elevated both *in-vivo* and *in-vitro*, and NaHS mitigated these effects. JNK-phosphorylation was upregulated in C2C12 cells after Hcy treatment, but NaHS could not reduce this effect. Apoptosis was induced after Hcy treatment, and it was mitigated by the NaHS supplementation in C2C12 cells.

HIF1-α, VEGF, PPAR-γ and p-eNOS expression levels were attenuated in skeletal muscle of CBS^{+/-} mice after 21 days of FAL in comparison to WT mice and were improved via the GYY4137 (another H₂S donor compound) treatment. Collateral vessel density and blood flow were significantly reduced in post-FAL CBS^{+/-} mice compared to WT mice, and these effects were ameliorated by the GYY4137 treatment. Plasma nitrite levels were decreased in post-FAL CBS^{+/-} mice compared to WT mice, and these were improved by GYY4137 supplementation.

I also noticed FOXO1-mediated MuRF-1 upregulation, which further degrades MHC-I in CBS^{+/-} mice compared to WT mice, and these effects were improved by NaHS intervention. Functional studies revealed that NaHS administration improved muscle fatigability in CBS^{+/-} mice.

This work provides evidence that H₂S is beneficial in mitigating HHcy-mediated skeletal muscle injury incited by oxidative or ER stress responses and H₂S might be employed as a potential therapeutic to alleviate the harmful metabolic effects of HHcy conditions.

CHAPTER I

OVERVIEW ⁽¹⁾

Homocysteine (Hcy) has been studied extensively for over 30 years for its unique involvement in an increasing number of human diseases (2-4). It is generated via methionine cycle (MET-cycle) and its level is controlled by two processes: around 50% of Hcy goes to the transsulfuration pathway to produce cysteine, and the other half is re-methylated back to methionine (MET) via the folate cycle (5-7) (Fig. 1). The normal total plasma Hcy concentration in the body is 5-15 μM , however, in a diseased condition, *i.e.*, hyperhomocysteinemia (HHcy), total plasma Hcy levels increase ($>15 \mu\text{M}$) (8). HHcy can be classified as moderate (15-30 μM), intermediate (30–100 μM) and severe ($>100 \mu\text{M}$) (7,8). There are mainly 4 ways humans can develop HHcy: (1) methionine-rich protein diet (9); (2) Vitamin B₁₂/folate deficiency (10); (3) heterozygous/homozygous for cystathionine- β synthase (11); and (4) obstruction of renal clearance (12).

Figure 1: Schematic representation of Hcy metabolism. (A) Dietary methionine is converted to homocysteine (Hcy) through S-adenosyl methionine (SAM) and S-adenosyl homocysteine (SAH) and then back to methionine (MET). Hcy also bifurcates to the transsulfuration pathway where it is converted to cysteine in presence of rate-limiting enzymes cystathionine- β synthase (CBS) and cystathionine- γ lyase (CSE). Cysteine generated through transsulfuration pathway is further converted to glutathione (GSH); (B) Conversion of cobalamin (Vitamin B12) to methyl-B12 in the presence of methionine synthase reductase (MTR) is necessary for remethylation of 5-methyl- tetrahydrofolate (THF) to THF; (C) Dietary folic acid (Vitamin B9) enters the folate cycle after its conversion first to dihydrofolate (DHF) and then to THF. The 5, 10-methyltetrahydrofolate reductase (MTHFR) is a key enzyme that converts 5, 10-methylene-THF to 5-methyl-THF.

HHcy has been associated with severe skeletal muscle dysfunction, but the precise mechanism(s) is still unknown (7,13-20). Children born with very high levels of Hcy, i.e., HHcy caused by a lack of functional CBS alleles, show severe dysfunction of the musculoskeletal system and die shortly after birth, but individuals that heterozygous for non-functional CBS mutations can survive (13). Previous studies reported that HHcy could cause disruption of Z-discs, fiber size, and excessive collagen deposition in muscle (15,20,21), but the pathways that trigger such pathological effects in skeletal muscles are not fully understood. Loss of skeletal muscle mass (muscle wasting) is mediated mainly by three processes: apoptosis, poor vasculature, and atrophy (protein degradation exceeds protein synthesis over time) (22,23). Therefore, identification of the precise molecular mechanism(s) regulating the processes underlying HHcy is essential to devise proper treatment strategies. Findings from our group and other groups determined that HHcy induces oxidative stress in endothelial cells (24), vascular

smooth muscle cells (25), liver tissue (26), and brain (27). Oxidative stress has been implicated in many diseases associated with protein misfolding and reduction of efficiency of protein folding pathways (28-33), but the cellular pathways that are involved in these stress-related conditions have not been elucidated. During severe ER-stress conditions, activated IRE1 recruits TNF receptor-associated factor 2 (TRAF2) and apoptosis signal-regulating kinase 1 (ASK-1), which further activates c-Jun N-terminal kinase (JNK) (34-36) (Fig. 2). However, whether HHcy can compromise cell survival via activation of JNK is not studied previously. AKT is a major survival factor promoting cell proliferation, and its dysregulation has been detected in muscle wasting (37-39). A previous study showed that activated JNK could induce inhibitory phosphorylation of IRS-1 at Ser³⁰⁷ (40). Since Ser³⁰⁷ phosphorylation promotes general inhibition of IRS-1 signaling, it suggests that JNK-activation may impair PI3K/Akt axis (41). JNK controls cell response to the harmful extracellular stimulus (42,43). JNK/c-Jun pathway regulates pro-apoptotic and pro-inflammatory gene expressions (44). Whether HHcy mediates oxidative and ER-stress responses, and whether this further induces apoptosis in muscle, has not been studied previously.

Figure 2: A schematic highlighting hyperhomocysteinemia mediated skeletal muscle dysfunction. HHcy can induce cell death via induction of ER and oxidative stress

responses that can lead to skeletal muscle cell death via JNK-activation and concurrent impairment of PI3K/AKT survival axis.

HHcy is implicated in vascular toxicity, causing endothelial cell damage and dysfunction (20,45-47). Although several markers of ER-stress, including CCAAT-enhancer-binding protein homologous protein (CHOP), have been shown to be increased in a model of skeletal muscle atrophy, whether HHcy mediated ER-stress can play a role in muscle atrophy is still unclear (48). Additionally, several models of atrophy showed that inhibition of PI3K/Akt signaling induces nuclear import of FOXO in regulating Atrogin-1 and MurF-1 expression (49,50). Some studies have already demonstrated that HHcy inhibits Akt activation in endothelial cells (47), but whether this similar mechanism can be attributed to muscle myopathy is yet to be explored (37).

H₂S is increasingly being recognized as an important signaling molecule in the cardiovascular and nervous systems via its ability to neutralize a variety of reactive oxygen species (ROS) (51-53), as well as via increased cellular glutathione (GSH) levels through activation/expression of γ -glutamylcysteine synthetase (54-61). Cystathionine γ -lyase (CSE) and CBS are the main H₂S producing enzymes, which produce H₂S from Hcy in the transsulfuration reaction (62). CBS gene mutation leads to dysfunction in endogenous H₂S biosynthesis (63), suggesting that patients with this mutation are more prone to oxidative stress-mediated damages due to malfunction in Hcy metabolism and inefficient H₂S biosynthesis (54). CBS is a crucial enzyme in the transsulfuration pathway, and heterozygous CBS deficient (CBS^{+/-}) mice show mild to severe endogenous elevation of circulatory Hcy levels (64-71) and lower levels of H₂S in their blood, which lead to oxidative stress-mediated damage (72,73). Hence, it is important to study the mechanism of exogenous supplementation of H₂S as a possible approach to mitigate the effects of HHcy condition in skeletal muscle myopathy.

In this study, I examine the potential mechanisms of HHcy-mediated oxidative

stress, ER stress, inflammation, apoptosis, angiogenesis, and atrophy in skeletal muscle, and whether H₂S has any beneficial role on mitigating these effects.

1. *Homocysteine and Hyperhomocysteinemia*

Homocysteine (Hcy) is a sulfur-containing non-proteinogenic amino acid that is produced during the metabolism of methionine (MET) via MET-cycle (2). Post absorption, MET is converted into S-adenosylmethionine (SAM) by ATP and catalyzed by methionine adenosyltransferase (MAT), leaving it with a transferrable methyl group. This methyl group is donated for cellular methylation requirements and becomes S-adenosyl-homocysteine (SAH). SAH hydrolase is an enzyme that reversibly hydrolyzes SAH and produces Hcy (74). Hcy is present in blood in three different forms: around 1% as free thiol, 70–80% as a disulfide-bound to a swath of plasma proteins, and the remaining 20-30% as a homo/heterodimerize with other thiols (3). Upon the generation of Hcy via the MET-cycle, 50% goes to the transsulfuration pathway for production of glutathione (GSH, an antioxidant) and the rest is re-methylated back to MET via the folate cycle as shown in Fig. 1 (2,5,6).

In healthy individuals, the generation and elimination of Hcy stays in balance; however, once this homeostasis is disturbed, it leads to HHcy (75). HHcy can be developed via consumption of an excess amount of MET-rich diet, vitamin B₁₂/folate deficiency, the occurrence of heterozygous/homozygous CBS gene mutation, and the obstruction of renal clearance (12). Besides these, genetic mutations in any Hcy metabolism pathway-regulated genes (e.g., 677C>T and 1298A>C in the *MTHFR* gene) can also lead to HHcy (14,76-78) (Table 1). Other determinants as well, such as age, sex, physical activity, alcohol intake, certain medications, and even different disease conditions can offset the rate of MET-cycle, thereby influencing the corresponding increase in the total Hcy levels in the blood (79). During HHcy, the MET-cycle is

generally dysregulated (80). This leads to disruption of multiple signaling pathways because it is the only pathway that gives rise to the production of essential methyl groups needed for the subsequent biosynthesis of cellular compounds such as creatine, epinephrine, carnitine, phospholipids, proteins, and polyamines and also the epigenetically governed cellular processes like methylation of DNA, RNA, and histones that are dependent upon Hcy metabolism (7,81). Although HHcy conditions can cause multi-organ pathologies via oxidative and ER-stress responses (7,20,82-84), the precise mechanisms of multi-organ pathology due to HHcy remain elusive.

Table 1. List of most prevalent genetic polymorphisms/mutations reported in HHcy and associated Diseases/Phenotypes.

Metabolism of Hcy depends on several factors, i.e., the level of methionine in the diet, SAM level and the type of cells in which methionine metabolism takes place (109). High SAM level can act as an allosteric inhibitor for methylenetetrahydrofolate reductase (MTHFR). MTHFR catalyzes the conversion of 5,10-MTHF to 5-MTHF, which is a co-substrate of Hcy in the remethylation reaction (110). Therefore, the presence of high SAM prevents Hcy from entering the remethylation pathway. High SAM level also acts as an allosteric activator CBS the transsulfuration pathway (111,112). Together it appears that the presence of high level of SAM favor Hcy entering to the transsulfuration pathway. However, only a few organs such as the liver, kidney, pancreas, brain, adipose tissue and small intestine express CBS (113,114). Vascular and muscle tissues don't express CBS, so the high SAM lead to transient accumulation of Hcy (82). Hcy metabolism also depends on dietary MET load (115-117). When diet contains a basal methionine level, Hcy cycles through remethylation pathway about 1.5-2.0 times before being directed towards the transsulfuration pathway, but when dietary methionine content is half the basal level, the cycling of Hcy via the remethylation pathway increases 2-fold (118). Conversely, when the dietary MET level is high, Hcy cycling through the remethylation is reduced by about 1.5-fold (118). High levels of intracellular Hcy exported out into the circulation (119); however, the exact mechanism of Hcy export is not identified yet. Although HHcy is found in ~5-7% of the general population and is associated with increased risk of cardiovascular disease, osteoporosis, skeletal muscle myopathy and other metabolic complications (7,20,82-84), the precise molecular pathways that lead to multi-organ dysfunction remain mostly unexplored.

2. *Skeletal muscle structure and functions*

Skeletal muscle is the largest organ (roughly 40 to 50% of the body's total weight in an average human), constitutes 50-75% of the body's total proteins (120-122). Muscle contains very long multinucleated cells (myocytes) that are bundled up and surrounded by connective tissues (123). Primary functions of skeletal muscle are: 1) production of contractile force that provides breathing, locomotion and postural support; and 2) thermogenesis during periods of cold stress (123). For force production, depending on the primary function of the muscle it consists of either fast twitch (type I) or slow twitch (type II) fibers (123). Type I fibers are used for repetitive, low-intensity functions, such as postural support (123). These fibers provide less force generation but are fatigue-resistant and have a higher reliance on oxidative metabolism and therefore have more density of mitochondria and oxidative enzymes (123). Type II fibers are divided into two fiber subsets: type IIx and type IIa (123). Type IIx fibers are very glycolytic and produce high contractile force but are susceptible to fatigue due to a lower mitochondrial density (123). Type IIa fibers are an intermediate fiber type (123). They provide a moderate contractile force and are more fatigue-resistant than Type IIx fibers (123).

Myocytes, unlike most other cell types, contain multiple nuclei and are striated because of contractile segments called sarcomeres (123). Within each muscle fiber, a structure called myofibril that contains the contractile protein of the muscle called actin and myosin (123). Actin filament consists of two additional proteins known as troponin and tropomyosin, which are used for contractile regulation (123). The striated regions, called sarcomeres, are within the myofibrils and consist of areas of myosin/actin overlap, as well as an area where myosin does not overlap with actin, called the H zone (123) (Fig. 3). Sarcomeres are divided by a wall of structural proteins, which makes up a region of the sarcomere called the Z line (123). Based on "sliding filament theory," during

contraction, the required energy comes from the de-phosphorylation of adenosine triphosphate (ATP), wherein myosin heads "cock" form cross-bridges with actin and then pivot inward towards the H zone (124), that ultimately decreases the sarcomere length from one Z line to another Z line (Fig. 3) (125).

Figure 3: Structure of a muscle fiber, organization of myofibril, and banding pattern.

Surrounding each myofibril is a network of channels that serve as a storage site for calcium, which is crucial for the regulation of muscle contraction (126). This structure is called the sarcoplasmic reticulum (126). The transverse tubules are another set of channels that pass through the muscle fiber (126). Each myocyte is connected to a branch of a motor neuron through a neuromuscular junction serving as the site of electrochemical transmission (127). Collectively, all the myocytes that are innervated by a single motor neuron are termed as a motor unit (127). Upon generation of an action potential high enough to cause contraction, the neural impulse is transmitted to the myocyte through the neuromuscular junction and is propagated down the transverse tubules to the sarcoplasmic reticulum, causing Ca^{++} to be released (128). Ca^{++} binds to the troponin molecule, which creates a shift in tropomyosin position (128). This allows for

exposure of the actin active sites and myosin-actin cross bridge formation, resulting in contraction (128).

In adults, repair of degenerated muscles relies on a small population of skeletal muscle stem cells known as satellite cells (129). Satellite cells, a population of quiescent muscle precursor cells, reside beneath the basal lamina, providing the predominant source of additional myonuclei for muscle growth (130,131). Once activated, satellite cells give rise to myoblasts that proliferate, differentiate, and fuse to form new muscle fibers or to repair damaged muscle fibers (132,133). The availability of a pool of myoblasts for myogenesis is essential for the development of muscle (134). The decreased number of muscle fibers could be due to the reduced myoblast proliferation or cytotoxicity (134). Moreover, in most cases, the apoptosis of myoblasts serves as a physiological behavior to remove excess myoblasts during myogenesis or muscle regeneration, while inappropriate apoptosis will pathologically lead to degeneration that is associated with various muscular dystrophies and atrophies (135,136). Therefore, identification of the molecular mechanism(s) of how high Hcy induced myoblast cytotoxicity is essential in understanding skeletal muscle growth, disease, and regeneration during HHcy condition.

3. *Hyperhomocysteinemia-mediated skeletal muscle pathophysiology*

HHcy is a known risk factor for vascular diseases (137); however, several studies also reported that HHcy leads to skeletal muscle weakness and functional impairment (5,15,20,21,46,66,82). Children born with severe homocystinuria due to CBS deficiency exhibit reduced body weight, skeletal muscle myopathy, and die teenage years (7)(5,15,20,21,46,66,82). Previous studies from our group showed that genetically modified HHcy mice (heterozygous for CBS gene deficiency) have lower body weights and less fatigue resistance and produce less contractile force, contain lower muscle ATP

levels, low dystrophin, and mitochondrial transcription factor A (mtTFA) (82). Similarly, in a study, Kanwar et al. [1976] found that HHcy can cause focal fragmentation, disruption, and smearing of the Z-discs and disorganization of the myofilaments in the skeletal muscles (15). This study also showed that HHcy could reduce cellular metabolic activity and induce energy imbalance in gastrocnemius rat skeletal muscle by decreasing the activity of pyruvate kinase, creatine kinase, and noticed increased activity of succinate dehydrogenase (18). Similarly, Veeranki et al. [2015] showed that Hcy affects fatty acid oxidation, affecting energy metabolism in skeletal muscle via PGC-1 α specific protein nitrotyrosylation and a concomitant reduction in association with PPAR- γ (82). On the other hand, many neurological disorders like amyotrophic lateral sclerosis (ALS) and multiple sclerosis affect muscle degeneration, and these medical conditions are also connected to HHcy (16). HHcy significantly lowers physical functions by deteriorating skeletal muscle functions in older compared to age-matched healthy subjects (138), which suggests that aging is one of the potential risk factors to be considered in this process (139).

Disorders, such as muscular dystrophy, sarcopenia, and immobilization, have been extensively researched. However, there is not enough data available considering the effects of HHcy on these conditions. Swart et al. [2013] demonstrated that in elderly individuals (~75.6 years of age), plasma Hcy levels had a strong inverse correlation with grip strength and functional capabilities (140). High Hcy levels resulted in poor grip strength in men and lowered functional ability including walking, climbing stairs and rising from a chair (140). In heterozygous CBS-deficient mice (CBS^{+/-}), a model of mild to moderate HHcy, it was observed that 28 days post-induction of hindlimb ischemia CBS^{+/-} mice displayed blunted hindlimb perfusion and lower collateral blood vessel development when compared to WT mice (46). This study also found that CBS^{+/-} mice had lower vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF1- α)

and peroxisome proliferator-activated receptor coactivator 1- α (PGC1- α) after 28 days of ischemic recovery when compared to controls (46). Below, I have summarized the findings relevant to oxidative/ER-stress, apoptosis, atrophy and poor angiogenesis caused by HHcy that might contribute to skeletal muscle dysfunction.

3.1. *HHcy-mediated oxidative/ER-stress responses in skeletal muscle*

During metabolic processes, a certain amount of pro-oxidative reactive oxygen species (ROS) are formed. The intracellular environment is predominantly a reducing environment due to the presence of enzymes like glutathione peroxidase (GPx), superoxide dismutase (SOD), and catalase (CAT), which break down ROS into water and oxygen. There are also a series of built-in redox defense systems that inactivate ROS, which include reduced glutathione (GSH), hydrogen sulfide (H₂S), nicotinamide adenine dinucleotide - hydrogen (reduced) (NADH), thioredoxin, and free radical scavengers such as Vitamins C and E (141-143). Oxidative stress occurs when there is an imbalance between free radical production and antioxidant capacity in a given cell. Previous studies revealed that Hcy contains a -SH group like other thiols (RSH) which can undergo oxidation to form a disulfide bond (RSSR) even at physiological pH in the presence of metal catalysts and molecular oxygen [O₂[•]] (21) (Fig. 4). Further, Hcy can also produce hydrogen peroxide (H₂O₂, a pro-oxidant molecule) during metal-catalyzed oxidation step and peroxynitrite (ONOO⁻, a potent oxidant) in the presence of nitric oxide (NO) and superoxide anion (⁻O₂[•]) (144). Findings from our group and others demonstrated HHcy effects on oxidative stress in cardiac microvascular endothelial cells (24), vascular smooth muscle cells (25), and the liver tissue (26). Although these phenomena have been studied in multiple tissue types, whether HHcy exerts its detrimental effects on muscle through similar mechanisms is not known.

Figure 4: Redox imbalance during hyperhomocysteinemia: (A) Homocysteine can homo/hetero-dimerize in the presence of transition metal catalysts and molecular oxygen to form superoxide radicals that are converted to H_2O_2 by superoxide dismutase (SOD) and which are in turn neutralized to H_2O and O_2 by glutathione peroxidase (GPx) and catalase (CAT).

Several studies have reported that HHcy creates oxidative stress that promotes apoptosis, inflammation, insulin resistance, and dysregulation of lipid metabolism in different organs (5,7,145,146). Moreover, increased ROS level due to HHcy can be involved in lipid peroxidation, protein denaturation, and DNA damage, which ultimately damage cellular components; modulates gene expression, alters cell signaling pathways, and energy imbalance (147). Besides, Hcy can also form Hcy-thiolactone and acetylates free amino groups in proteins, which further intensify the exaggerated oxidative stress condition (146). DiBello et al. [2010] showed that proteins (PRDX1, PRDX2, and HSP90AA) which are produced as a response to oxidative stress were significantly upregulated in the liver during HHcy (148). One study showed that production of ROS was ameliorated by PPAR- γ activation in ECs (146), as reported previously from our laboratory indicating that PPAR γ was reduced in HHcy condition

(148), suggesting that PPAR- γ can be used as a potential target to mitigate oxidative stress during HHcy. HHcy lead to oxidative stress and that interferes with different cellular signaling pathways in various organs; therefore, it suggests that HHcy may have similar pathological effect in muscle tissue.

Oxidative stress has been implicated in many diseases associated with protein misfolding pathways (28-33). Indeed, a study by Malhotra et al. [2008] showed that antioxidants reduce endoplasmic reticulum (ER) stress and improve protein secretion in Chinese hamster ovary (CHO)-H9 cells (149). Similarly, a study using differential display analysis in HUVECs found that GRP78 (78-kDa glucose-regulated protein) was upregulated in Hcy-treated HUVECs compared to controls (150). GRP78 is a chaperone protein belonging to the HSP70 family and predominantly resides in the lumen of the ER (151). HHcy can induce ER-stress (33), but which pathways get affected by this condition is poorly understood. It is known that after translation protein folding occurs inside ER, but during stress conditions, misfolded proteins accumulate inside the ER-lumen and induce unfolded protein response (UPR) (152). UPR increases transcription of chaperone genes to facilitate protein folding, helps to attenuate the translation process, and finally, it degrades misfolded proteins accumulated in ER (153-155). In the mammalian system, UPR is mediated through inositol-requiring protein 1 (IRE1), PRKR-like ER kinase (PERK), and activating transcription factor 6 (ATF6) (156). IRE1 promotes X-box binding protein 1 (XBP1) mRNA splicing, which finally activates ER chaperones (e. g. BiP/GRP78, EDEM, and ERdj4). PERK phosphorylates eukaryotic translation initiation factor 2 α (eIF2 α), and that stops translation. ATF6 regulates the expression of chaperone genes and ER-associated degradation (ERAD) genes (157-159). Several studies showed that HHcy could exacerbate ER-stress by reducing the efficiency of protein folding pathways and increasing the production of misfolded proteins (28). ER-stress might play a key role in mediating adverse effects during the HHcy

condition in muscle (160).

In the mammalian system, there are two isoforms of IRE1: IRE1 α and IRE1 β . Both of these proteins are transmembrane proteins and contain a Ser/Thr kinase domain and an endoribonuclease domain (161,162). In a stress-free environment, IRE1 α remains in an inactivated form bound with GRP78; however, in stress condition, it dissociates from GRP78 and gets auto-phosphorylated (163). Then the endonuclease activity of activated IRE1 α cleaves a 26bp intron from ubiquitously expressed XBP1u mRNA. Removal of this intron causes a frameshift in the XBP1 coding sequence, resulting in the translation of XBP-1s isoform (152). XBP-1s encodes a specific basic leucine zipper-containing transcription factor, known as X-Box Binding Protein-1 (XBP1) to promote cell survival (163-165). However, during severe ER-stress conditions, IRE1 α recruits' TNF receptor-associated factor 2 (TRAF2) and apoptosis signal-regulating kinase 1 (ASK-1), then activates c-Jun N-terminal kinase (JNK) and induces apoptosis (34-36). Although many studies also reported bidirectional regulation of ER-stress in apoptosis through JNK activation, and concomitant attenuation of cell proliferation and protein synthesis via PI3K/AKT axis (166-168), it is unknown whether HHcy exerts its detrimental effect in muscle through this similar mechanism pathway (Fig. 5).

Figure 5: HHcy-mediated cellular stress responses. (A) HHcy-mediated excessive production ROS impaired biogenesis, as well as protein folding process leading to ER-stress, (B) Activation of IRE1 α during ER-stress response, causes XBP1 mRNA splicing. During severe ER-stress condition activated IRE1 α recruits' TNF receptor-associated factor-2 (TRAF2) along with apoptosis signal-regulating kinase-1 (ASK1), which further activate c-Jun N-terminal kinase (JNK). (C) Activated JNK phosphorylates c-Jun, that recruit activator protein-1 (AP-1) to the promoter sequences of various pro-apoptotic and pro-inflammatory genes and induce cell deaths. (D) JNK is also involved in the phosphorylation of IRS-1 at Ser³⁰⁷ which in turn inhibits IRS-1 signaling thus impairing the PI3K/AKT axis and interfere with cell survival.

3.2. HHcy-mediated cell death pathways

Apoptosis is programmed cell death and is required for normal development; however, a very high amount of apoptotic cell death due to environmental stress can be detrimental (169). Excessive apoptosis is observed in many well-known disease states such as ischemic heart disease, AIDS, Alzheimer's, and Parkinson's, etc. (170-172).

Apoptosis occurs in 2 phases; namely, the death decision phase and execution phase. Death decision phase is controlled by two proteins, such as pro-apoptotic (Bax and Bak) and anti-apoptotic proteins (BCL-XL and BCL-2). The execution phase is regulated by caspases (proteolytic enzymes), responsible for the execution of apoptosis after the death decision is confirmed (173). Unlike necrosis, apoptosis occurs at a single cell level (173). Studies showed that an increase in oxidative stress could lead to caspase activation (174-177). This oxidative stress-mediated apoptosis was further supported by other studies demonstrating that anti-oxidants such as N-acetylcysteine (NAC) treatment could block apoptosis in a similar way that caspase inhibitors do (178,179). Several mechanisms(s) have been proposed pointing to the fact that oxidative stress generated by HHcy can lead to multiorgan pathologies (5,7,145,146). This argues that stimulus no other than redox imbalance during HHcy is capable of inducing apoptotic cell death. Even though findings have suggested that HHcy could be causal in a wide range of disorders including skeletal muscle myopathy; however, whether Hcy mediates skeletal muscle myopathy via inducing different types of cell deaths (apoptotic, necrotic and pyroptotic) are needed to identify.

Studies showed that Hcy induced apoptotic cell death in ECs (180,181). A previous finding revealed that Hcy causes apoptosis in HUVECs via activation of UPR, which was mediated through IRE1 activation (182). Similarly, another study suggested that Hcy can induce trophoblast cell death during embryonic development (183). Hcy was also found to induce apoptosis in bone marrow mesenchymal stem cells (BMSCs) via oxidative stress mediated JNK activation (184). Folate deficiency, which is one of the causes of HHcy found to induce apoptotic cell death in RINm5F pancreatic Islet β -cells, through oxidative-nitrosative stress (185)(186). Mesangial cell apoptosis via inducing ROS and p38-MAPK activation had also been reported (187). Hcy induces apoptosis via upregulation of DNA damage response in neurons; this process is mediated through

PARP activation, and p53 induction (188). Our lab using genetically engineered heterozygous CBS deficiency mouse model (CBS^{+/-}) reported that HHcy causes cell death via upregulation of mitochondria-mediated cell death pathway (BAX, caspase-9, and caspase-3) (189). Hydrogen sulfide (H₂S) is known to be involved in the modulation of many physiological pathways. A study found that H₂S-releasing sildenafil (ACS6) treatment could protect HHcy-mediated apoptosis in PC12 cells (190).

3.3. *HHcy-mediated dysregulation of angiogenesis*

Although many studies have been conducted to identify the possible mechanism(s) of skeletal muscle myopathy, fewer studies have demonstrated the potential risk factors that inhibit skeletal muscle adaptability in response to chronic ischemia. Poor angiogenic capacity is known to play a vital role in skeletal muscle adaptability (191,192). Lack of revascularization is already reported in elderly frailty and in many metabolic disorders, where metabolic factors and associated signaling pathways are found to be involved in a variety of skeletal muscle dysfunctions (193). Besides these, HHcy is well-studied in the cardiovascular system where it has been shown to increase oxidative stress in vascular tissue and cause dysfunction of ECs (194,195).

The purpose of capillaries is to serve as the interface for delivery of oxygen and removal of metabolites to/from tissues. Angiogenesis is a physiological process where new blood vessels form from the pre-existing ones (191). Angiogenesis plays a vital role during tissue injury/wound repair, endometrial cycle, and muscle adaptation to stress/exercise (196). Previous studies demonstrated that HHcy impairs angiogenesis in multiple tissues (197-201). During angiogenesis, the main angiogenic signal is vascular endothelial growth factor (VEGF). VEGF production is mainly up-regulated in a tissue under hypoxic conditions via inducing hypoxia inducing factor 1 α (HIF1 α) and that plays

a pivotal role in angiogenesis. VEGF binds to VEGF receptor (VEGFR) on ECs' surface which goes through promotes ECs' growth and migration towards the source of VEGF (202). Upon VEGF binding to VEGFR, PI3K is also activated leading to activation of the protein kinase Akt, which in turn phosphorylates eNOS and increases NO production during angiogenesis as shown in Fig. 6. Akt activation can also promote endothelial proliferation and cell survival.

Figure 6: Hypoxia mediated angiogenesis via VEGF/Akt axis. Under hypoxic condition, VEGF production is up-regulated in tissue under hypoxic conditions via inducing hypoxia inducing factor 1 α (HIF1 α) and that plays a pivotal role in angiogenesis via activating multiple angiogenic signaling cascades for endothelial cell proliferation, migration, and survival.

An early study showed that Hcy treatment on chicken embryos (embryonic day 3.5) caused inhibition of early extraembryonic vascular development, altered

composition of the vascular beds, and reduced VEGF-A and VEGFR-2 expression (200). Similarly, when HUVEC cells were treated with Hcy, it reduced cell proliferation and viability, induced a G1/S arrest, and attenuated the cell migration and tube-like formation on Matrigel (201). This study showed that this effect is mediated through VEGF/VEGFR, Akt, and ERK1/2 inhibition (201) as shown in Fig. 6. Similarly, a study demonstrated that Hcy inhibits angiogenesis by preventing proliferation and migration of ECs in a dose-dependent manner (199). In an *in-vivo* rat model, it was reported that HHcy impaired ischemia-induced angiogenesis and collateral vessel formation, which is partly mediated through the reduction in bioactivity of endogenous NO (197). Several groups showed that Hcy-mediated defective angiogenesis is largely due to decreased GPx expression and a consequent increase in oxidative stress, leading to endothelial progenitor cell dysfunction (203,204), reduction of the bioavailability of NO (205,206) and dysregulation of matrix metalloproteinases (MMPs) (207,208).

Previous studies showed that high Hcy can be toxic to endothelial cells and can induce endothelium dysfunction may be via hypomethylation of specific genes (209-212). It also noticed that Hcy affects ECs via inhibiting cyclin A (213). When they transduced cyclin A in ECs, the inhibitory effect of Hcy was rescued. These studies have been conducted in an *in-vitro* system; however, there is much less evidence reported for the *in-vivo* system. As Akt has been associated to involved in ECs proliferation, migration and survival during angiogenesis and HHcy found to inhibit Akt activation in ECs, however, whether these two processes potentiate muscle atrophy is not studied yet (37,45).

3.4. *HHcy-mediated skeletal muscle atrophy*

As mentioned earlier, skeletal muscle is the largest organ in our body, containing 50-75% of the body's proteins. Loss of skeletal muscle mass is commonly referred to as

muscle atrophy. Several E3 ubiquitin ligases such as MuRF1, MAFBx (Atrogin-1), Nedd4.1, TRAF6, and MUSA1 have been identified to mediate proteolytic degradation of both thick and thin filament proteins in skeletal muscle atrophy (214,215). Forkhead Box (FOX) proteins are a group of transcription factors with a conserved DNA binding domain and are responsible for regulating a number of E3-ubiquitin ligases upon a variety of cellular stress responses (216-219). Studies showed that in the absence of growth factors or in the presence of external stress (oxidative/ER-stress), PI3K/Akt pathway activation decreases and JNK activation increases; which promote nuclear localization of Foxo (216,220-223) as shown in Fig. 7. Although nuclear localization of FOXO stimulates MuRF-1 and Atrogin-1 expression, and that induces muscle atrophy (224), however, whether HHcy also causes skeletal muscle atrophy via this similar mechanism was not studied (Fig. 7).

Figure 7: Schematic model of HHcy-induced muscle atrophy via nuclear translocation

of FOXO. In HHcy condition, JNK activation may be upregulated and Akt-activation may be downregulated, which promotes nuclear localization of FOXO and reduced activation of mammalian target of rapamycin (mTOR). Nuclear localization promotes upregulation of MuRF-1 and Atrogin-1, which finally degrade muscle proteins. Whereas reduced activation of mTOR reduced protein synthesis. Muscle atrophy causes, when protein degradation exceeds over protein synthesis over time.

It has been reported that HHcy is associated with a decline in physical performance and skeletal muscle dysfunction in genetically engineered CBS deficient mice (CBS^{+/-}) (5,20,82). Skeletal muscle dysfunction and poor physical performance can result from a reduction of muscle mass and/or structural and metabolic alteration (Fig. 7) (139,225,226). Indeed, a study found that cystathionine γ -Lyase-deficient mice have lethal myopathy and oxidative injury, wherein dietary cysteine supplementation could mitigate this effect (84). Another group reported patients with HHcy due to methyltetrahydrofolate reductase (MTHFR) mutations (C677T and A1298C) showed poor survival and muscle pain in these patients (227). Similarly, a study from our group concluded that vasodilation in skeletal muscle arterioles is decreased during HHcy due to reduced expression of gap junction proteins such as connexins 37, 40 and 43, and increased expression of myostatin in the skeletal muscle (228).

4. Effect of hydrogen sulfide on hyperhomocysteinemia-mediated skeletal muscle myopathy

Hydrogen sulfide (H₂S) is increasingly being recognized as a novel endogenous gasotransmitter like nitric oxide (NO) and carbon monoxide (CO) (54,59,229). Being a potent anti-apoptotic/anti-necrotic (230,231), anti-inflammatory (232) and cytoprotective agent (233), H₂S plays crucial roles in physiological homeostasis wherein it reduces

oxidative damage (51,234). As mentioned earlier, high SAM level can act as an allosteric inhibitor for MTHFR in the remethylation pathway (110) and allosteric activator for CBS in the transsulfuration pathway (111,112). Together these results suggest that the presence of a high level of SAM favors Hcy entering into the transsulfuration pathway; however, in patients with CBS mutation, a high SAM level builds up (due to MET load) leading to transient accumulation of Hcy and reduction of H₂S levels. The endogenous H₂S production ranges from 1–10 pmoles per second per mg protein (235). Patients with CBS mutation have a high amount of Hcy and tend to produce a lesser amount of H₂S (63,236), suggesting that these patients are likely more prone to oxidative stress-mediated damage (54). Studies revealed that endogenous H₂S could modulate multiple signaling pathways, upregulate endogenous antioxidant systems and exert additive effects with known antioxidants (234), suggesting that exogenous supplementation of H₂S could be employed as a beneficial strategy to improve redox imbalance owing to HHcy (Fig. 8).

(A) Generation of endogenous H₂S

(B) H₂S serves as a scavenger of free superoxide radicals

(C) Reduction of proteins' disulfide bonds by H₂S

Figure 8: Salubrious effects of H₂S on cellular biochemistry. (A) Being an important antioxidant molecule H₂S helps synthesize cysteine which gets converted into GSH via CBS and CSE enzymatic pathways. (B) H₂S is a potent scavenger for a variety of reactive oxygen species (ROS). (C) H₂S is known to reduce disulfide bonds in proteins and thereby it may reverse the homocysteinylation of proteins during HHcy conditions.

4.1. The effect of Hydrogen sulfide on oxidative/ER-stress responses

Multiple studies demonstrated the cytoprotective effects of H₂S in different *in-vitro* models, all relating to its ability to neutralize a variety of reactive species (25,237,238) and reduction of a disulfide bond in proteins (54,239) (Fig. 8). H₂S in water dissociates into H⁺, HS⁻, and S²⁻ ions. HS⁻ has a capacity to scavenge ROS. H₂S itself has also been recognized to be a reducing agent, as it can react directly with and quench the superoxide anion (O₂^{•-}) (240,241) and free radicals like peroxynitrite (242) as well as

other ROS *in-vitro*. Micro concentrations of H₂S generated from Na₂S/NaHS was found to neutralize free oxyradicals (243), peroxynitrite (237), hypochlorous acid (238) and homocysteine (25) in *in-vitro* condition. There is no sulfide receptor in mammalian cells that is responsible for the biological actions of sulfide, hence sulfide, as a thiol with strong reducing activities, may also be a redox-controlling molecule similar to other small thiols, such as cysteine and GSH (237,244). A study by Kimura et al. (2004) using primary cultures of neurons, found that H₂S increases the cellular GSH levels by enhancing the activity of gamma-glutamylcysteine synthetase and up-regulating cystine transport (244). Similarly, another study reported that 100 µM NaHS induces glutamate uptake by assisting glial glutamate transporter-1 (GLT-1) and enhances cysteine transport and GSH synthesis (245). In support of this effect, multiple studies demonstrated that H₂S induces the cellular GSH in the brain (246), spinal cord (247), heart (248), lung (249), kidney (250), liver (249), and gastrointestinal tract (251,252). Moreover, recent reports suggested that H₂S could attenuate cellular oxidative stress by improving activities of CAT (248,253-255) and GPx (256-258).

Many studies showed that H₂S attenuates ER-stress in numerous tissue types. A study found that H₂S attenuated HHcy-induced cardiomyocytic ER-stress in rats (259). Whereas, Li et al. (2015) demonstrated that H₂S protected against myocardial ischemia/reperfusion injury in rats by inhibiting ER-stress (260). Likewise, another study also reported that H₂S exerts its protection against the neurotoxicity of formaldehyde by overcoming ER-stress in PC12 cells (261).

4.2. *The effect of Hydrogen sulfide on cell death pathways*

In addition to an anti-oxidant effect of H₂S, several studies also proposed that it has the ability to reduces cell death in various tissue types. An *in-vitro* study using nucleus pulposus (NP) from patients with lumbar disc herniation showed that exogenous

H₂S donor attenuated hypoxia (generated by CoCl₂ treatment) induced apoptosis in primary NP cells (262). Similarly, a study using a rat model found that H₂S mitigates cigarette smoke-induced apoptosis via reducing ER-stress (263). H₂S was also reported to decrease Hcy-mediated ER-stress and apoptosis in the hippocampus of rats by enhancing the BDNF-TrkB pathway (264). In support of this, NaHS supplementation was shown to significantly inhibit hypoxia-induced neuronal apoptosis through inhibition of ROS (mainly H₂O₂)-activated Ca²⁺ signaling pathway in mouse hippocampal neurons (265). In another study, it was observed that H₂S attenuated gentamicin-induced apoptosis via reducing ROS moiety in normal rat kidney-52E cells; they found the protein levels of Bax, Caspase-3, and cleaved-caspase-3 were decreased while the expression of Bcl-2 was increased (266). Similarly, NaHS (H₂S donor) administration significantly inhibited the early phosphorylation of JNK and decreased the number of apoptotic cells, lowered cytochrome C release and enhanced Bcl-2 expression in cardiomyocyte after ischemia-reperfusion (I/Re) injury (267). H₂S also attenuated 1-methyl-4-phenylpyridinium ion (MPP (+))-induced apoptosis in PC12 cells by attenuating an overproduction of intracellular ROS (268). Exogenous NaHS (H₂S donor) also shown to ameliorate early brain injury after subarachnoid hemorrhage (SAH) by inhibiting neuronal apoptosis (268).

4.3. *The effects of Hydrogen sulfide on angiogenic defect*

It has been reported that H₂S is also involved in vasodilation, vascular protection, regulation of blood pressure and many other functions (54,57-59,61). Like other gasotransmitters (CO and NO), H₂S can rapidly travel to vascular tissues without any transporter exerting a host of biological responses. Two independent groups reported using either transformed endothelial cell line (RF/6A) or HUVECs that H₂S induces proliferation and migration of these cells (269,270). The pro-angiogenic effect of H₂S is

further supported by the increase in tube-like structure formation in ECs in *in-vitro* Matrigel assays (269,270). H₂S exerts angiogenic effects via releasing VEGF in both SMCs (smooth muscle cells) and ECs (271,272). Some *in-vivo* studies demonstrated that H₂S induced a concentration-dependent increase in the length and complexity of the vascular network (269,270). When ECs were exposed to H₂S donors, it activated multiple signaling pathways, such as PI-3K/Akt and MAPK pathways during neovascularization (269,270). Further evidence for H₂S-mediated VEGF induction during angiogenesis was reported in an ex-vivo mouse aorta sprouting assay, where the VEGF-induced angiogenesis was markedly suppressed in aortic rings of the CSE deficient mice (CSE^{-/-}) (270). In an alternative pathway, exposure to H₂S increased calcium levels in ECs, which led to eNOS activation and increased NO release during angiogenesis (273-275).

4.4. *The effects of Hydrogen sulfide on muscle atrophy*

Skeletal muscles are now considered to be an endocrine organ, synthesizing and secreting a variety of bioactive molecules including inflammatory cytokines, growth factors, adipokines, carnitine and more recently H₂S (276). In this context, H₂S appears to protect against low oxygen and nutrient supply as well as ischemic injury in multiple organs including skeletal muscles (276-278). In agreement with this view, it was hypothesized that dysregulation of H₂S metabolism is involved in chronic fatigue syndrome (CFS), also called myalgic encephalomyelitis (279). One of the cellular targets of H₂S is potassium (K_{ATP}) channel (280,281). K_{ATP} channel activation has been suggested to be involved in the prevention of calcium overload and preservation of myofibre integrity during exercise, recovery from muscle fatigue, rather than in normal muscle contractility and excitability (282,283). Similarly, a significant decrease in H₂S content in muscle fibers together with a reduction in SOD1 expression was presented in

a rat model of skeletal muscle ischemia-reperfusion (I-R) injury (276).

CHAPTER II

HYPOTHESIS AND SPECIFIC AIMS

Key Objective

The objective of this study was to determine the effects of hyperhomocysteinemia on skeletal muscle myopathy and investigate if H₂S can attenuate these effects.

Hypothesis

The central hypothesis of this proposal is that HHcy causes skeletal muscle myopathy by inducing apoptosis, inflicting muscle atrophy and compromising angiogenesis via JNK-activation and concomitant impairment of PI3K/AKT axis, and H₂S mitigates these effects (Fig. 9).

Specific Aim#1: To determine whether HHcy induces ER-stress and apoptosis via JNK-phosphorylation, effect(s) of H₂S treatment in mitigating this induction.

Specific Aim#2: To determine whether the Hcy-activated JNK downregulates angiogenic pathways via inhibiting AKT-phosphorylation and H₂S treatment ameliorates these pathway(s).

Specific Aim#3: To determine whether Hcy instigates muscle atrophy via up-regulation of E3 ubiquitinligases through JNK/AKT axis and H₂S attenuates muscle atrophy

Figure 9: A basic model of my hypothesis

CHAPTER III

HYDROGEN SULFIDE ALLEVIATES HHcy-MEDIATED OXIDATIVE AND ER-STRESS RESPONSES IN SKELETAL MUSCLE ⁽²⁸⁴⁾

INTRODUCTION

Homocysteine (Hcy) is a sulfur-containing non-proteinogenic amino acid that is generated during methionine metabolism via the methionine cycle (MET-cycle) (285). In healthy subjects, synthesis and elimination of Hcy are balanced; however, if Hcy metabolism is disturbed, then its plasma levels are elevated, leading to hyperhomocysteinemia (HHcy) (20,82-84,286). Although children born with functional CBS deficiency show severe HHcy and die in their teenage years (13,15,20), the molecular mechanism(s) how HHcy triggers such pathological effects in skeletal muscle is not fully understood.

Previous studies revealed that Hcy contains a -SH group like thiols (RSH) which can undergo oxidation to form a disulfide (RSSR) even at physiological pH in the presence of metal catalysts and molecular oxygen [$O_2^\bullet$] (21). Further, Hcy can also produce hydrogen peroxide (H_2O_2 , a pro-oxidant molecule) during metal-catalyzed oxidation step and peroxynitrite ($ONOO^-$, a powerful oxidant) in the presence of nitric oxide (NO) and superoxide anion ($\cdot O_2^-$) (144). Although these phenomena have been studied in multiple tissue types, whether HHcy exerts its detrimental effects on muscle through these mechanisms is not yet elucidated. Oxidative stress has been implicated in many diseases associated with protein misfolding (29-31). Likewise, studies have also reported that HHcy could induce ER-stress in hepatocytes as well as in vascular

endothelial and aortic smooth muscle cells, but the cellular pathways that are involved in these stress-related conditions are not adequately studied (32,33). It is well-known that after translation, the protein folding occurs inside the ER, but during stress conditions, misfolded proteins can accumulate inside ER-lumen inducing the unfolded protein response (UPR) (152). In mammals, there are three branches of UPR: inositol-requiring enzyme-1 (IRE1); PRKR-like ER kinase (PERK); and activating transcription factor-6 (ATF6) (153,154,156). During severe ER-stress conditions, activated IRE1 α recruits' TNF receptor-associated factor-2 (TRAF2) and apoptosis signal-regulating kinase-1 (ASK1), which further activate c-Jun N-terminal kinase (JNK) (34-36). Activation of JNK phosphorylates c-Jun at Ser63 and 73 residues in NH₂-terminal (287,288). Upon activation, the phosphorylated JNK translocate to the nucleus where it phosphorylates c-Jun (289,290). JNK along with c-Jun makes up the activator protein-1 (AP-1) transcription factor, which involved in the transcription of some pro-apoptotic and pro-inflammatory genes (291-296). JNK also regulates maturation and activity of T cells in addition to the synthesis of pro-inflammatory cytokines, such as interleukin-2 (IL-2), IL-6 and TNF- α (297-299). Whether HHcy can compromise muscle survival via JNK activation is not currently known.

Chronic systemic inflammation and apoptosis are the important driver for muscle wasting, that can be dysregulated by HHcy condition (300). These cytokines work synergistically promoting muscle atrophy due to the cross-talk between inflammatory cells and organs, resulting in reduced protein synthesis and increased protein degradation, and ultimately leading to muscle loss and functional impairment. Therefore, identification of the precise molecular mechanism(s) as to how these cytokines are regulated during HHcy is essential to devise future preventive strategies.

H₂S is increasingly being recognized as an important signaling molecule in the cardiovascular and nervous systems via its ability to neutralize a variety of reactive

oxygen species (ROS) (25,237,238) and to reduce disulfide bonds (54,239).

Cystathionine γ -lyase (CSE) and CBS can irreversibly remove Hcy by converting it into H₂S, since patients with CBS lack H₂S, making them vulnerable to oxidative stress-mediated damages (54). Hence, the purpose of my study was to understand the effect(s) of HHcy-mediated oxidative and ER-stress responses in muscle and the beneficial effects of an H₂S donor (NaHS) employing both *in-vitro* (C2C12 cells) and *in-vivo* model (CBS^{+/-}) systems. My results indicate that H₂S could be developed as a potential therapeutic target in various forms of musculopathies wherein HHcy is linked with metabolic dysfunction.

MATERIALS AND METHODS

Animal maintenance and diet protocol. Male wild-type (WT, C57BL/6J) and CBS^{+/-} (B6.129P2-Cbstm1Unc/J 002853) mice were purchased from the Jackson Laboratory (Bar Harbor, ME) (71). All animals were ~8-12 weeks-old and maintained in 12:12 h light–dark cycle with regular mouse chow diet in the animal facility of the University of Louisville. All animal protocols and care were carried out according to the guidelines of National Institute of Health (NIH Pub. No. 86–23, revised 1985) and were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of Louisville. Animals were divided into 4 experimental groups: (1) Wild-type C57BJ/L6 mice (WT); (2) CBS^{+/-} heterozygous mice fed with methionine (CBS+Met); (3) NaHS-supplemented wild-type mice (WT+NaHS); (4) NaHS-supplemented CBS^{+/-}+Met mice (CBS+Met+NaHS). Mice were treated with NaHS for 8 weeks (30 μ M/kg/day, I.P.) and fed with a methionine-enriched and low-folate, low Vitamin B6, and low Vitamin B12 diet (Cat. No. TD 97345; Harlan Teklad, Madison, WI, USA) (301-304). WT mice were given 0.9% normal saline (vehicle control) and fed with normal chow (Purina Farmer's Exchange, Framingham, MA, USA).

Rationale for choosing the experimental mice. Homozygous for CBS knock out (KO) mice (CBS^{-/-}) mice die shortly after their birth, whereas heterozygous for CBS KO mice (CBS^{+/-}) survive but they show low Hcy levels in their blood (5-10 μ M, Fig. 15D). So, in the present study, I treated CBS^{+/-} mice with high met diet to examine the effects of HHcy condition (>40 μ M, Fig. 16F) on skeletal muscle (301-304).

Genotyping analysis of the heterozygous CBS^{+/-} mouse. After purchasing, mice were cross-bred, yielding around 10 % CBS^{-/-}, 60 % CBS^{+/-}, and 25 % CBS^{+/+}. For genotyping, tail samples were collected, genotypic analysis was performed using PCR by targeted disruption of the CBS gene. The PCR products were run on 1.2 % agarose gel (prepared in TAE buffer, pH 8.4) in the presence of ethidium bromide and the images recorded in a gel documentation system (305). CBS^{+/-} heterozygote gene-positive mice produced two bands (450 and 308 bp), while CBS^{+/+} (WT) mice represented only one band (308 bp).

Reagents and antibodies. Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS) were purchased from American Type Culture Collection (Manassas, VA, USA) and trypsin EDTA was from VWR (Radnor, PA, USA). ECL reagent and polyvinylidenedifluoride (PVDF) membrane were from Bio-Rad (Hercules, CA, USA). Dihydroethidium (DHE) was purchased from Thermo Fisher Scientific (Waltham, MA, USA). All other reagents and chemicals were ordered from Sigma–Aldrich or available highest grade.

The antibodies for GRP78 (Cat. No.# sc-13968), IRE1 α (Cat. No.# sc-20790), ATF6 (Cat. No.# sc-22799), X-box binding protein (XBP1) (Cat. No.# sc-7160), rabbit anti-mouse (Cat. No.# sc-358914), mouse anti-rabbit (Cat. No.# sc-2357), and mouse anti-goat (Cat. No.# sc-2354) were ordered from Santa Cruz Biotechnology (Dallas, TX, U.S.A). The antibody for GAPDH (Cat. No.# MAB374) was ordered from EMD Millipore (Burlington, MA, USA). Rest of the antibodies for p-IRE1 α (S724) (Cat. No.# ab48187),

p-JNK (T183/Y185) (Cat. No.# ab4821), t-JNK (Cat. No.# ab85139), p-cJun (S73) (Cat. No.# ab30620), and t-cJun (Cat. No.# ab32137) were ordered from Abcam (Cambridge, MA, USA), and used for Western blots analysis as per the manufacturers' protocols.

Cell culture and treatments. The C2C12 cells (immortalized mouse myoblast cell line, ATCC) were cultured in Corning® T-75 flasks in ATCC-formulated DMEM (catalog No. 30-2002) supplemented with 10% FBS, 0.1% of penicillin and streptomycin at 37 °C with 5% CO₂. The C2C12 cells were grown to 80% confluence and were plated for 4 different experimental groups: Group 1: CT (PBS as vehicle control); Group 2: Hcy (1mM); Group 3: Hcy+NaHS (250 µM); and Group 4: NaHS. In this study, we used 1mM Hcy and 250µM NaHS concentrations for the individual treatments (20,246). A stock solution of Hcy, NaHS were prepared by directly dissolving in basal DMEM medium (serum-free media). Following 24 h of treatment as mentioned earlier, cells were processed for qPCR, Western blot, DHE-staining, and other biochemical analysis.

Total RNA extraction. Total RNA was extracted from muscle samples and cells using a Trizol method (306). In brief, first equal volume of Trizol was added in the sample and incubated for 10mins in 25°C. Then 200µl of chloroform was added and incubated for 10mins on ice. After that, samples were centrifuged at 12000g for 15mins at 4°C and carefully collected the top layer in a new Eppendorf tube containing 500uL of prechilled isopropanol. Then samples were centrifuged at 12000g for 20mins at 4°C and pellets were collected in DEPC water. Total RNA quality was determined by NanoDrop ND-1000, and RNA with high purity (260/280~2.00 and 260/230~2.00) was used for q-PCR.

Reverse transcription and real-time quantitative PCR (RT-qPCR). Reverse transcription was performed according to the manufacturer's protocol using high-capacity cDNA reverse transcription kit from Applied Biosystems (Foster City, CA, USA) for the primer sequences listed in Table 2. For RT-qPCR, SYBR green-based kit was used to measure the relative expression of each mRNA specific primers. Briefly, 3 steps cycling protocol

was performed using 20 ng of cDNA template in a 20µL reaction volume under the following conditions: denaturation at 95 °C for 15 min followed by 40 cycles of 94 °C for 15 s, 55 °C for 30 s, and 70 °C for 34 s in which fluorescence was acquired and detected by Roche LightCycler® 96 Real-Time PCR System (Roche Diagnostics, IN, USA). Following RT-qPCR, analysis of melt curve was performed to validate the specific generation of the expected PCR product. GAPDH was used as an endogenous control (Quanta Biosciences, Beverly, MA, USA).

Genes	Forward Primers	Reverse Primers
GRP78	5'-ATTGGTGGCCGTTAAGAATG-3'	5'-CAGTGTTGTCTCGGCCAGTA-3'
ERN1	5'-CCCAAATGTGATCCGCTACT-3'	5'-TTGAGAGAATGCAGGTGTGC-3'
ATF6	5'-GGCCAGACTGTTTTGCTCTC-3'	5'-CCCATACTTCTGGTGGCACT-3'
XBP1	5'-TGAATGGCCCTTAGCATTTTC-3'	5'-CACAGAACAGGACGCTGTGT-3'

Table 2. List of primers used for RT-qPCR experiments for chapter IV.

Western blotting. All protein expressions of both tissues and cells were assessed by Western blotting (307). Briefly, all protein lysates were made in RIPA buffer, which was supplemented with PMSF (1 mM), Na-orthovanadate (1 mM) and a protease inhibitor cocktail (10 µl/ml of lysis buffer). The protein samples were estimated by Bradford assay. Equal amounts of protein (50 µg) were resolved on SDS-PAGE (8%, 10%, 12%) and transferred onto a polyvinylidene difluoride (PVDF) membrane. The blots were visualized using ECL Luminata Forte (Millipore, Temecula, CA, USA) in a Bio-Rad ChemiDoc system. The band intensity was normalized to GAPDH for all the proteins and quantified using the Bio-Rad's Image Lab software (Bio-Rad, Hercules, CA, USA).

Total Homocysteine measurement. The total tHcy levels were measured from plasma of experimental mice using homocysteine assay kit (Crystal Chem, IL, USA) as per manufacturer's instructions.

Intracellular ROS imaging by confocal scanning microscopy. The cell permeable fluorescent dye dihydroethidium (DHE) was used to detect intracellular ROS (72). In brief, after treatment C2C12 cells were incubated in DHE (10µM/L) for 20 minutes in a humidified chamber at room temperature in the dark. At the end of the incubation, cells were washed with PBS and fluorescence images were scanned using a laser confocal microscope (Olympus FluoView1000, Pittsburgh, PA, USA) (72). Fluorescent intensity was quantified using ImageJ software (<https://imagej.nih.gov/ij/>).

Assessment of lipid peroxidation. Malondialdehyde (MDA), a metabolite of lipid peroxidation and an indicator of oxidative stress was measured as the previously described method by Okhawa et al. (308). Briefly, after treatment, the cells were washed with PBS, followed by sonication (5 Amps/ 5 mins) and centrifugation at 13000 rpm for 10 minutes. To the supernatant 100 µl of 8.1% SDS, 20% acetic acid, and 0.8% thiobarbituric acid were added. The samples were incubated at 95°C for 60 minutes, and then 100µl of deionized H₂O and 100µl of 1-butanol were added. After spinning at 4000 rpm for 10 minutes, the top layer was collected in 96 wells plate and read at a wavelength of 532 nm. The OD values were plotted against the known standard to determine the intracellular malondialdehyde levels.

Assessment of hydrogen peroxide and total ROS. H₂O₂ was measured from cells by Amplex red assay kit (Invitrogen, Cat no. A22188) according to the manufacturer protocol. Whereas, 2', 7'-dichlorofluorescein diacetate (2',7'-DCFDA) assay kit (Abcam, Cat no.-ab113851) was used for total cellular ROS detection. In brief, after treatment cells were washed two times with PBS and incubated with a 10 µM DCFDA probe for 15 mins in serum-free media. Final fluorescence intensity was measured in a microplate

reader (Ex, Em= 485, 535nm).

Measurement of GSH/GSSG ratio. Assessment of GSH vs. GSSG ratio was carried out in all 4 treatment groups using GSH/GSSG ratio detection kit (Abcam, Cat no.- ab138881) according to the manufacturer protocol.

Assessment of pro-inflammatory cytokines. Multi-analyte enzyme-linked immunosorbent assay (ELISA) kit (Qiagen, Germantown, MD, USA) was used following the manufacturer's protocol to measure all the pro-inflammatory cytokines (IL1 α , IL2, IL4, IL6, IL12A, IFN- γ , and TNF- α).

Cell viability assay. Cell viability was determined by MTT assay (309). In brief, after treatment as described above, all media was aspirated and 100 μ l MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] reagent solution was added in each well after diluting MTT reagent (5 mg/mL) in basal media. The cells were then incubated for 4 h at 37°C and then washed with PBS. After that, 100 μ l of DMSO was added to each well to dissolve the cell membrane and bring formazan into the solution. The absorbance values were taken at 570 nm by Spectramax 3000 spectrophotometer (Molecular Devices, Sunnyvale, CA, USA).

Flow cytometry. C2C12 cells were grown in 12 well plates until 70% confluence and treated as mentioned above. After 48 h, the cells were harvested with 150 μ l trypsin-EDTA (Corning) and 600 μ l DMEM complete medium to neutralize the trypsin. The cells were collected in a 1.5 ml Eppendorf tube and spun at 2000 rpm for 5 minutes, and the supernatant was discarded. Then cells were washed 2 times with complete DMEM media to remove any traces of trypsin and then resuspended in 1x binding buffer (Sigma apoptosis kit: Cat # APOAF). The cells were then stained with Annexin V and Propidium Iodide (PI) according to manufacturer's instructions and subjected to flow cytometric analysis (Accuri cytometers Inc. Ann Arbor, MI, USA).

Statistics. All values are expressed as mean $\pm$ s.e.m. The overall difference between the

experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Whereas, unpaired t-test was used for comparison between two groups. The threshold for significance was set at $p < 0.05$, and a minimum of 3 biological replicates were used for each experiment. For all statistical calculation, GraphPad Prism (Ver 7, GraphPad Software) was used.

RESULTS

Hcy induces oxidative stress in C2C12 cells. DHE-staining results showed that Hcy significantly induced ROS in C2C12 cells as compared to vehicle controls (PBS treated), whereas, NaHS treatment mitigated the effects of Hcy (Fig. 10A). To detect intracellular total ROS levels, I used DCFDA fluorescent probe (an indicator for superoxide-, peroxide- and peroxynitrite-mediated oxidative chemistry). A similar finding was also observed in the levels of total ROS in Hcy treated cells compared to controls as measured by a fluorometric method (Fig. 10B). Hcy treatment showed significant induction of H_2O_2 production in C2C12 cells, and it was reduced by NaHS (Fig. 10C). Similarly, malondialdehyde levels (a marker of lipid peroxidation) was significantly increased upon Hcy treatment in C2C12 cells, and NaHS reversed this effect (Fig. 10D). Furthermore, a significant reduction in GSH/GSSG ratios in Hcy treated C2C12 cells as compared to controls, whereas NaHS treatment was found to successfully attenuate this effect (Fig. 10E).

Figure 10: NaHS protects against Hcy-induced oxidative stress in C2C12 cells (immortalized mouse myoblast cell line). (A) 1mM Hcy treatment for 24h resulted in the generation of cellular oxidative stress in C2C12 cells as detected by dihydroethidium (DHE)-staining. Images captured using confocal microscope are on the left and their quantification on the right (under 60x, bar=20µm), where n=3 technical replicates; (B) Hcy treatment induces total ROS levels as detected by 2',7'-H₂DCFDA (2',7' – dichlorofluorescein diacetate) probe, where n=4 technical replicates; (C) Hcy exposure induces H₂O₂ production measured by Amplex red assay kit, n=3 technical replicates; (D) Hcy treatment induces lipid peroxidation measured by Malondialdehyde (MDA) assay, where n=3 technical replicates; (E) Hcy treatment reduces GSH vs. GSSG ratio, where n=3-4 technical replicates. The overall difference between the experimental groups was determined by one-way, and a Tukey's post hoc analysis was run when

overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and *p<0.05 vs. CT and #p<0.05 vs. Hcy.

HHcy induces ER-stress responses in skeletal muscle. To examine whether HHcy induces ER-stress via redox imbalance mechanism, I performed Western blot analyses on samples from both *in-vitro* and *in-vivo* models. Results showed that Hcy significantly induced ER-stress markers such as GRP78, ATF6 and p-IRE1 α and that the effect was mitigated by NaHS in C2C12 cells as shown in Fig. 11A and 11B. However, I did not notice any significant changes in XBP1 protein levels after Hcy treatment (Fig. 11A and 11B). In addition, the ratios of p-IRE1 α /t-IRE1 α were found to be significantly induced in C2C12 cells after Hcy treatment compared to controls, whereas NaHS supplementation attenuated this effect (Fig. 11C). In the qPCR analysis, I noticed mRNA levels of GRP78, ATF6, IRE1 α , and XBP1 were also increased significantly in post Hcy treatment of C2C12 cells compared with vehicle controls, these effects were also mitigated by NaHS (Fig. 11D). In addition, my *in-vivo* model revealed similar type of changes in Western blots and qPCR data from the protein samples collected from hindlimbs gastrocnemius muscle (Fig. 11E-H).

Figure 11A-D: High Hcy mediates ER-stress response in muscle cells *in-vitro*. (A) Western blots analysis showing Hcy treatment induces ER-stress markers, such as GRP78, ATF6, p-IRE1α (S724), t-IREα and XBP1, whereas NaHS treatment mitigates this effect, where n=3 technical replicates; (B) Densitometric measurement of ER-stress markers from above Western blots images are shown in the bottom, where n=3 technical replicates; (C) Quantification of p-IRE1α/t-IREα ratio from Western blots images are shown on the right, where n=3 technical replicates; (D) Hcy induced expression mRNA levels of GRP78, ATF6, IRE1 α and XBP1 in C2C12 cells (log transformed), where n=3 technical replicates. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m, and *p<0.05 vs. CT and #p<0.05 vs. Hcy.

Figure 11E-H: High Hcy mediates ER-stress response in muscle *in-vivo*. (E) Western blots analysis showing induced expression of ER-stress markers, such as GRP78, ATF6, and p-IRE1α (S724), t-IREα in CBS+Met mice compared to WT mice; whereas NaHS treatment mitigates this effect, where mice number (n)=4 in individual group; (F) Densitometric quantification of Western blots of above ER-stress markers shown on the bottom, where mice number (n)=4 in individual group; (G) Densitometric analysis of pIRE1α/t-IREα ratio from Western blots is shown on the right, where mice number (n)=4 in individual group; (H) The q-PCR analysis shows that mRNA levels GRP78, ATF6, IRE1α, and XBP1 (log-transformed data) were increased in skeletal muscle of CBS+Met mice compared to WT mice, where mice number (n)=4 in individual group. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant

difference occurred in group means. Data are shown as mean $\pm$ s.e.m and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

Hcy enhanced JNK-phosphorylation. To confirm whether high oxidative and ER-stress responses can induce JNK-phosphorylation during HHcy condition, I did Western blotting for p-JNK. I found that Hcy significantly induced phosphorylation of JNK in comparison with controls; however, I did not find a concomitant reduction in JNK-phosphorylation via NaHS treatment as shown in Fig. 12A and 12B. To study whether JNK-phosphorylation is mediated via ER-stress mechanism(s), I also treated cells with tunicamycin (as a known ER-stress inducer). Results revealed that JNK-phosphorylation was inhibited by SP600125 (JNK-inhibitor) and induced by tunicamycin (positive control). Similar results were observed in phospho-c-Jun levels (a downstream target of JNK).

Figure 12. High Hcy induces JNK-phosphorylation in both *in-vitro* and *in-vivo* models. (A) Western blots data showing Hcy mediated JNK-phosphorylation and induced protein expression of p-cJun (S73) in C2C12 cells, where SP600125 was used as a JNK inhibitor, and Tunicamice was used as a positive control, where n=3 technical replicates; (B) Densitometric measurements of pJNK/t-JNK, and p-cJun/t-cJun ratios from Western blots images are shown on the right, where n=3 technical replicates. The interaction between multiple groups was determined by one-way or two-way ANOVA, including a Tukey's post hoc analysis when significant interaction occurred. Data are shown as mean±s.e.m., and *p<0.05 vs. CT and #p<0.05 vs. Hcy; (C) Western blot data showing Hcy mediated JNK-phosphorylation and induced protein expression of p-cJun (S73) in CBS+Met mice compared to WT mice, where mice number (n)=4 in individual group; (D) Densitometric measurements of pJNK/t-JNK and p-cJun/t-cJun ratios from Western blots images are shown on the right, where mice number (n)=4 in individual group. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

Similarly, I noticed JNK-phosphorylation was induced in skeletal muscle of CBS+Met mice compared to WT mice, and interestingly this effect was mitigated via NaHS supplementation (Fig. 12C and 12D).

HHcy induced pro-inflammatory milieu in CBS+Met mice. To identify whether HHcy-mediated oxidative and ER-stress responses could modulate pro-inflammatory cytokines via JNK/cJun axis, I measured levels of these cytokines in plasma samples collected from experimental mice. Results showed that IL1 α , IL2, IL4, IL6, IL12A, IFN- γ , and TNF- α were elevated in CBS+Met in comparison with WT mice (Fig. 13). IL6 and TNF- α levels were found to be significantly induced in plasma of CBS+Met as compared to the WT mice.

Figure 13. HHcy induced pro-inflammatory milieu in CBS+Met mice *in-vivo*. The levels of inflammatory cytokines such as IL1 α , IL2, IL4, IL6, IL12A, IFN- γ , and TNF- α were elevated in the plasma of CBS+Met mice in comparison to WT mice. The difference between these two groups were determined by unpaired t-test. Data are shown as mean $\pm$ s.e.m. and where mice number (n)=4 in individual group and *p<0.05 vs. WT.

Hcy induced cell death involves apoptosis. First, to check the cell viability after Hcy treatment, I performed MTT assay. Results showed that Hcy significantly reduced cell viability after 24 h and 48 h. Although I did not find significant improvement of cell viability in Hcy treated C2C12 cells after 12h and 24 h of NaHS treatment, I noticed NaHS improved cell viability significantly after 48 h (Fig. 14A). To identify whether HHcy-mediated oxidative and ER-stress responses could induce apoptosis via JNK/cJun axis, I also did flow cytometry analysis after staining with Annexin V and propidium iodide (PI). Similarly, I found Hcy induced apoptosis in C2C12 cells as compared to controls after 48 h, whereas NaHS treatment substantially mitigated this effect as shown in Fig. 14B and 14C.

Figure 14. NaHS protects against Hcy-induced C2C12 cells death. (A) Hcy treatment induces C2C12 cell death after 24 h and 48 h. Cells were treated in 4 experimental groups (CT, Hcy, Hcy+NaHS, and NaHS) for 12h, 24h and 48h before being subjected to MTT assay, where n=4 technical replicates; (C) Flow cytometry for studying C2C12 cell death by apoptosis. Representative images of PI and Annexin V expression on C2C12 cells surface, where n=4 technical replicates; (D) Quantification of apoptotic cells were determined by total percentage of cells which were Annexin V⁺ and PI⁺, where n=4 technical replicates. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m., and *p<0.05 vs. CT and #p<0.05 vs. Hcy.

DISCUSSION

Previously studies reported that HHcy was detrimental to skeletal muscle (20); however, molecular mechanisms underlying the detrimental effects of HHcy on muscles were not precisely studied. To my knowledge, this is the first study elaborating the

mechanistic roles of Hcy during oxidative and ER-stress responses, which can potentiate skeletal muscle dysfunction via apoptosis, and inflammation through JNK-phosphorylation.

Previous findings demonstrated the effects of HHcy on oxidative stress in cardiac microvascular endothelial cells (145), vascular smooth muscle cells (25), and liver tissue (26). The results from the present study add to the growing body of evidence that HHcy can, in fact, induce pathological changes in muscles via inducing ROS moieties. In this study, I also noticed lipid peroxidation and H_2O_2 levels are equally elevated, and GSH/GSSG ratio was reduced by Hcy in C2C12 cells. NaHS treatment was found to improve all these conditions (Fig. 10). These results suggest that HHcy in CBS mice due to heterozygous CBS deficiency is equally detrimental to skeletal muscle compared to WT mice, which may result from higher ROS generation.

Although oxidative stress has been implicated in many diseases encompassing protein misfolding and the disruption of protein folding pathways (28-31), to my knowledge this is the first study showing that HHcy could also induce ER-stress response in skeletal muscle (Fig. 11). This finding also corroborates the previous observations showing that HHcy mediates higher ER-stress responses in endothelial cells (150,310,311). A study by Malhotra et al. indicated that antioxidants reduced ER-stress leading to improved protein secretion (149). Similarly, I also noticed that NaHS treatment has a beneficial effect towards mitigating ER-stress response in skeletal muscle (Fig. 11).

JNK pathway is known to control cellular response to harmful extracellular stimuli (42,43,312). Whether Hcy-mediated oxidative and ER-stress responses can also induce similar effects in skeletal muscle was not studied previously. I found JNK phosphorylation was upregulated in C2C12 cells after Hcy treatment, but NaHS could not reduce this effect. Whereas, my *in-vivo* data showed that JNK-phosphorylation was

successfully mitigated via NaHS intervention. Since I only studied a single readout (24 hrs post-HHcy treatment) in *in vitro* settings, I may have missed an acute Hcy-mediated effect on the JNK-phosphorylation. In the *in-vivo* CBS model, I was able to observe the continuous or prolonged effect of the NaHS mediated phospho-JNK status. I noticed the apoptosis rate was induced in C2C12 cells after Hcy treatment and it was mitigated by the NaHS supplementation (Fig. 14). Furthermore, reduction of apoptosis after NaHS treatment confirmed the ability of H₂S to alleviate the effects of Hcy. Moreover, this study shows that HHcy-mediated upregulation of pro-inflammatory cytokines (TNF- α , IL-1, and IL-6) in plasma of CBS+Met mice compared to WT mice (Fig. 13). My results are also in agreement with inflammatory bowel disease conditions wherein JNK-upregulation plays a vital role (312). Oudi and colleagues reported a similar inflammatory response in acute coronary syndrome (ACS) patients, where tHcy, HsCRP, IL-6 and TNF α were significantly elevated (313). In addition to these findings, studies from other groups have reported that HHcy causes cardiovascular disease via increasing IL-1ra and IL-6 levels (314,315). Furthermore, it's possible that during inflammation immune cells (CD8+ T lymphocytes) may cause myocyte degeneration (autoimmune responses) in the muscle (14,316).

HHcy is known to cause hypermethylation of genes (7); however, I did not test the possibility of methylation status that may and may not be a factor in HHcy mediated apoptosis and inflammatory responses. From this study it is not still confirmed whether NaHS mediating its effects via oxidative stress mechanisms or something else and whether other antioxidants (like N-acetylcysteine) has similar effects like NaHS. Further work is required that might throw light to explore the possible molecular mechanism(s) of the actions of H₂S and whether it could be developed as a potential therapeutic target for treating skeletal muscle dysfunction and related metabolic disorders.

CHAPTER IV

HYDROGEN SULFIDE IMPROVES POST-ISCHEMIC ANGIOGENIC DEFECT IN THE HINDLIMB OF CYSTATHIONINE- β -SYNTHASE MUTANT MICE ⁽³¹⁷⁾

Introduction:

Homocysteine (Hcy) has been studied extensively in the last 30 years for its unique involvement in an increasing number of human diseases (2-4). The Hcy level is controlled by two major processes: around 50% of Hcy enters the transsulfuration pathway to produce cysteine, and the other half is re-methylated back to methionine via the folate 1-carbon cycle (5,6). Normal total plasma Hcy concentration in our body ranges from 5-15 μ M; however, in a diseased condition, such as in hyperhomocysteinemia (HHcy), plasma total Hcy levels are increased ($>15 \mu$ M) (8). HHcy can be classified as moderate (15-30 μ M), intermediate (30–100 μ M) and severe ($>100 \mu$ M) (8). Notably, there are 4 ways people can develop HHcy: (1) consumption of a methionine-rich protein diet; (2) vitamin B₁₂/folate deficiency; (3) presence of heterozygous/homozygous status for cystathionine- β synthase (CBS^{+/-}/CBS^{-/-}); and (4) obstruction of renal clearance (12). Apart from these factors, genetic variants in Hcy metabolism enzymes such as 677C>T and 1298A>C in *the MTHFR* gene can also lead to HHcy (14,76-78). There are also several other drivers like age, sex, physical activity, alcohol intake, certain medications and different disease conditions

(such as type 2-diabetes) that can also modulate the functioning methionine cycle, leading to an increased total Hcy concentration in the blood (79). HHcy has been associated with severe skeletal muscle dysfunction (7,13-20), but the precise mechanism(s) is still unknown. Previous studies found that HHcy causes endothelial cell (EC) injury (209), inhibition of EC proliferation (318), reduction of bioavailability of vasoregulatory mediators (such as NO and endothelin) (319), and induction of oxidative/ER-stress (24,33,320). How HHcy reduces neovascularization in the skeletal muscle is not precisely known.

The growth of new blood vessels from the preexisting vascular network is known as angiogenesis. When oxygen supply is low in a tissue or organ, it activates HIF1 α , which sends a signal to the nearest blood vessel, activating eNOS and producing NO needed for vasodilation. VEGF increases permeability and separates pericytes leading to the degradation of the basement membrane, thereby activating metalloproteases such as MMP-2 and 9 (321). These changes lead to EC proliferation and a concomitant migration in order to form new blood vessels (322). In recent years, it has been shown that PPAR- γ might be involved in angiogenesis via growth factors and cytokines that in turn stimulate migration, proliferation, and survival of these ECs (323).

PPAR- γ belongs to the nuclear hormone receptor superfamily; when specific ligands bind to the ligand-binding domain of PPAR- γ , a conformational change releases the bound corepressors (324,325). This allows co-activators like PGC-1 α and other coactivators to be recruited to the PPAR- γ responsive gene promoters thereby promoting the PPAR- γ -mediated transcription (81,326,327). HHcy reduces PPAR- γ expression in ECs (148). Studies have shown that PPAR- γ could regulate angiogenesis via upregulating VEGF (323) and that can further activate eNOS (328). Although, previous works showed that HHcy impaired neoangiogenic growth in muscle via reduction of HIF1 α and VEGF levels, whether PPAR- γ plays any role in this process had

not been studied (46).

H₂S is increasingly being recognized as an important signaling molecule in cardiovascular and nervous systems via its ability to neutralize a variety of reactive oxygen species (ROS) (51-53), and via increased cellular GSH levels through activation of gamma-glutamylcysteine synthetase, and reduction of the disulfide bonds (54-61,329). CBS and CSE are the main H₂S generating enzymes, producing H₂S from Hcy in the transsulfuration pathway (330). Patients with CBS deficiency tend to produce a lesser amount of H₂S (63,236), suggesting that these patients are likely more prone to oxidative stress-mediated damages due to excessive production of Hcy (54). A study revealed that endogenous H₂S could induce mRNA and protein expression of PPAR- γ , indicating that exogenous H₂S supplementation could be employed as a beneficial strategy to improve angiogenesis defect in HHcy patients (331). Hence the purpose of my study was to answer the following questions: (i) Does HHcy inhibit angiogenesis via downregulation of angiogenic signals like HIF1 α and VEGF in 21 days of post-FAL hindlimb of CBS^{+/-} mice? (ii) Does HHcy inhibit PPAR- γ expression which can further downregulate VEGF/eNOS signaling in the post-FAL hindlimb of CBS^{+/-} mice? And finally, (iii) Does GYY4137 (an H₂S donor) treatment improve angiogenesis via PPAR- γ /VEGF axis after 21 days of FAL in the hindlimb of experimental CBS^{+/-} mice?

CBS is one of the key enzymes in the transsulfuration pathway; heterozygous CBS deficiency (CBS^{+/-}) has proved to be a useful model for analyzing the effects of mild to a severe endogenous elevation in the levels of Hcy (64-71). Hence, in this study, I used CBS^{+/-} mouse model to identify the effect(s) of HHcy on angiogenesis in the skeletal muscle and evaluate whether exogenous administration of GYY4137 could improve this effect(s). Results indicate that H₂S could be developed as a potential therapeutic agent to treat the neoangiogenic defects in skeletal muscle wherein HHcy is linked with a barrage of metabolic dysfunctions.

MATERIALS AND METHODS

Animal maintenance, genotyping and diet protocol. Male WT (C57BL/6J) and CBS^{+/-} (B6.129P2-Cbstm1Unc/J 002853) mice were purchased from the Jackson Laboratory (Bar Harbor, ME). All animals were ~8-10 weeks-old and maintained in 12:12 h light-dark cycle with regular mouse chow diet in the animal facility of the University of Louisville. All animal protocols and care were carried out according to the guidelines of National Institute of Health (NIH Pub. No. 86–23, revised 1985) and were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of Louisville, KY, USA.

After purchasing, mice were cross-bred, yielding around 10 % CBS^{-/-}, 60 % CBS^{+/-}, and 25 % CBS^{+/+}. For genotyping, tail samples were collected, and DNA was isolated using DNeasy Blood & Tissue Kits (Qiagen, Germantown, MD, USA). Genotypic analysis was performed using PCR by targeted disruption of the CBS gene (representative images from each group of post-FAL mice are shown in Fig. 15A and genotyping in Fig. 15B). CBS^{+/-} heterozygote mice produced two bands (450 and 308 bp), while wild-type (CBS^{+/+}) mice represented only one band (308bp). Animals were divided into 4 experimental groups: (1) Wild-type C57BJ/L6 mice (WT), (2) CBS^{+/-} heterozygous mice (CBS) (3) GYY4137-supplemented CBS^{+/-} (CBS+GYY), (4) GYY4137-supplemented wild-type mice (WT+GYY). 0.25 mg GYY4137/kg body weight of mouse was applied by intraperitoneal injection every day for a total 21 days after femoral artery ligation (FAL) surgery, while the WT mice were given 0.9% normal saline (vehicle control) (72).

Femoral artery ligation (FAL). To create a hypoxic condition femoral artery ligation (unilateral) was performed under intraperitoneal pentobarbital sodium (50 mg/kg) anesthesia (50,51). Briefly, after separation of the femoral artery from the vein and

nerve, it was ligated using 6-0 silk suture at proximal and distal places (keeping same distance in all animals). I used separate mice groups [WT, CBS, CBS+GYG, and WT+GYG] as sham control where I performed the full process of surgery except the ligation. The skin was sutured using 6-0 silk thread. After the skin closure, betadine was applied. After recovery, laser Doppler blood perfusion was carried out to confirm the induction of ischemia.

Laser-Doppler tissue perfusion imaging and flowmetry. MoorLDI (Moor Instruments) was used to measure tissue perfusion intensity and blood flow rates (332). In brief, after anesthesia, a part of skin in hind limb was opened and blood flow measurement was taken for 2mins keeping same laser pointer in all experimental mice.

Barium angiograms. To determine angiogenesis, barium sulfate angiography was performed in mice (333). In brief, after pentobarbital anesthesia mice were infused with barium sulfate (0.1 g/mL) in 50 mM Tris-buffer (pH 5.0) at a constant flow (~1 ml/min) and pressure with a syringe pump through the common carotid artery. Heparin (20U/ml) was used along with barium sulfate to visualize the nascent angiogenesis. Angiograms were captured using the Carestream whole animal X-ray imaging system (Carestream Molecular Imaging, Woodbridge, CT) (334) and the vessel density was quantified using VesSeg tool (Institute for Signal Processing, University of Luebeck, Lübeck, Germany).

Reagents and antibodies. All reagents and chemicals were ordered from Sigma–Aldrich or available highest grade.

The antibodies for HIF1 α (ab51608), VEGF (ab51745) and eNOS (ab66127) were ordered from Abcam (Cambridge, MA, USA). Whereas PPAR- γ (sc-7273), p-eNOS Ser¹¹⁷⁷ (sc-12972), rabbit anti-mouse (sc-358914), mouse anti-rabbit (sc-2357), and mouse anti-goat (sc-2354) were from Santa Cruz Biotechnology (Dallas, TX, USA). The antibody for GAPDH (MAB374) was from EMD Millipore (Burlington, MA, USA), and

used for Western blots analyses as per the manufacturers' protocols.

Western blotting. Protein expressions were assessed by Western blots (72). Briefly, at the time of sacrifice, gastrocnemius muscle from the ischemic leg of each mouse was quickly removed, snap-frozen, and stored at -80 °C until further use. Protein from samples was extracted by homogenizing in the ice-cold RIPA buffer (Boston BioProducts, Worcester, MA, USA) containing 1 mM Phenylmethylsulfonyl fluoride (Sigma, Saint Louis, MO, USA), 1% protease inhibitors cocktail (Sigma, Saint Louis, MO, USA) and then sonicated employing the Sonifier 450 (Branson Ultrasonics, Danbury, CT, USA) using 3 x 5 sec at setting "3". The homogenates were centrifuged $17,400 \times g$ for 20 min at 4 °C, and the supernatants were quickly stored at -80 °C until further use. The protein contents were estimated by the Bradford assay. Equal amounts of proteins (50 µg) were resolved on SDS-PAGE (8%, 10%, 12%) and then transferred to polyvinylidene difluoride (PVDF) membranes. The respective blots were incubated with primary and secondary antibodies before visualizing them using the ECL Luminata Forte (Millipore, Temecula, CA, USA) in a Bio-Rad ChemiDoc system. The intensities of the bands were normalized to the housekeeping GAPDH for all the proteins examined. The quantification was performed using Image Lab™ Software (Bio-Rad, Hercules, CA, USA).

Reverse transcription and real-time quantitative PCR. Total RNA was extracted from muscle samples using a Trizol method as mentioned in chapter III (306). Then RNA quality was determined by NanoDrop ND-1000, and RNA with high purity (260/280~2.00 and 260/230~2.00) was used for q-PCR analysis. Reverse transcription was performed according to the manufacturer's protocol using high-capacity cDNA RT kit from Applied Biosystems (Foster City, CA, USA) for the primer sequences listed in Table 3. For RT-qPCR, SYBR green-based kit was used to measure the relative expression of each mRNA specific primers. Briefly, 3 steps cycling protocol was performed using 20 ng of

cDNA template in a 20 µL reaction volume under the following conditions: denaturation at 95 °C for 15 min followed by 40 cycles of 94 °C for 15 s, 55 °C for 30 s, and 70 °C for 34 s in which fluorescence was acquired and detected by Roche LightCycler® 96 Real-Time PCR System (Roche Diagnostics, Indianapolis, IN, USA). Following RT-qPCR, analysis of melt curve was performed to validate the specific generation of the expected PCR product. GAPDH was used as an endogenous control (Quanta Biosciences, Beverly, MA, USA).

Genes	Forward Primers	Reverse Primers
HIF1α	5'- TCAAGTCAGCAACGTGGAAG-3'	5'- TATCGAGGCTGTGTGCGACTG-3'
VEGF	5'- CAGGCTGCTGTAACGATGAA-3'	5'- CAATTTGGCTCCTCCTACCA -3'

Table 3. List of primers used for RT-qPCR experiments for chapter V.

Total plasma Homocysteine, hydrogen sulfide, and nitrite measurement. Blood samples were collected in tubes containing a 1/10 volume of 3.8% sodium citrate from each mouse by cardiac puncture after euthanasia. Then plasma was isolated by centrifugation at 2500 × g for 15 mins at 4 °C. Total plasma Hcy concentrations were measured in samples using the homocysteine assay kit (Crystal Chem, IL, USA) as per manufacturer's instructions.

Plasma H₂S was measured as a previously described method (208). In brief, samples were centrifuged at a speed of × 11,000 g for 10 minutes. 100 µl aliquots from the plasma were mixed separately with PBS (350 µL) and Zn(O₂CCH₃)₂ (1% W/V, 250 µL)

in a micro-centrifuge tube and sealed immediately. Then, N, N-dimethyl-p-phenylenediamine sulfate (20 mM, 133 μ L) in 7.2 M HCl, and FeCl₃ 30 mM, 133 μ L) in 1.2 M HCl was added to the mixture, sealed and incubated at 37°C for 45 min. After that, Trichloroacetic acid solution (10% w/v, 250 μ L) was added to the mixture to terminate the reaction. After centrifugation ($\times$ 2,700 g for 5 mins), 200 μ L supernatant was transferred to a 96-well plate and the absorbance was measured at 670 nm in a spectrophotometer. H₂S levels were calculated against a calibration curve of known concentrations of NaHS (0.01 - 100 μ mol/L).

Both nitrite and nitrate from the plasma was measured by a Griess reagent as (301). Briefly, equal volume of Griess reagent [0.1 % N-(1-naphthyl) ethylenediamine dihydrochloride, 1 % sulfanilamide, and 2.5 % phosphoric acid] was added to 100 μ L of samples and controls [sodium nitrite (NaNO₂)] (0.01-100ug). Then samples were incubated at 37 °C for 30 min and absorbance was recorded at 542 nm in a Spectra Max M2 plate reader.

Statistics. All values are expressed as mean $\pm$ s.e.m. The interaction between groups was determined by one-way or two-way ANOVA, including a Tukey's post hoc analysis when significant interactions were observed. The threshold for significance was set at $p < 0.05$, the total number of mice (n)= 4-5 were subjected to experimentation from each group. For statistical analyses, GraphPad Prism (Ver 7, GraphPad Software) was used.

RESULTS

The phenotypic feature and genotype of WT and CBS^{+/-} mice are depicted in Fig. 15A and 15B respectively. In this study, I noticed that CBS mice had significantly lower body weights in comparison to WT mice; however, I did not see any difference in body weights between CBS vs. WT after GYY4137 treatment for 21 days (Fig. 15C). I

observed CBS mice had significantly higher levels of plasma tHcy compared to WT mice, GYY4137 supplemented CBS mice also had similarly higher plasma tHcy levels as that of the CBS mice (Fig. 15D). After 21 days of GYY4137 treatment, I examined the plasma H₂S concentrations in the experimental mice. Results showed that plasma H₂S levels were significantly lower in the CBS mice compared to that of the WT mice as expected (Fig. 15E). However, after administration of GYY4137 for 21 days plasma H₂S levels were significantly elevated in both the CBS and WT mice (Fig. 15E).

Figure 15. Phenotypic and genotypic characteristics of experimental mice groups. (A) Hindlimb images after 21 days of GYY4137 treatments; (B) Genotyping of experimental mice; (C) Body weight measurements of experimental mice, where mice number (n)=4 in individual group; (D) tHcy measurements from the plasma of experimental mice, where mice number (n)=4 in individual group; (E) H₂S measurements from the plasma of

experimental mice, where mice number (n)=4 in individual group. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and statistical difference *p<0.05 vs. WT and #p<0.05 vs. CBS. (tHcy=total homocysteine, FAL=femoral artery ligation).

As a marker of a hypoxia induction in post-FAL hindlimb, I measured the HIF1 α levels by Western blotting. I noticed that HIF1 α levels were downregulated in post-FAL CBS mice in comparison to WT mice, GYY4137 treatment was found to mitigate this effect (Fig. 16A). To confirm mRNA expression of HIF1 α , I did qPCR analysis, and it did not show any significant decrease in mRNA levels of HIF1 α in post-FAL CBS mice compared to post-FAL WT (p=0.4824), GYY4137 treatment could not improve the mRNA levels in post-FAL CBS mice (p=0.9781) (Fig. 16B). I found that the protein expressions of VEGF and PPAR- γ were reduced in post-FAL CBS mice as compared to post-FAL WT mice, whereas this effect was improved after GYY4137 administration (Fig. 16A). Additionally, in the qPCR analysis, I found mRNA expression of VEGF was significantly reduced in the post-FAL CBS mice compared to post-FAL WT mice (p=0.0365); however, this effect was not improved upon GYY4137 administration (p=0.2139). I did not notice any significant change in the mRNA expression of PPAR- γ among the 4 experimental groups (Fig. 16B). I did not find any difference in proteins and mRNA levels for HIF1 α and VEGF among individual groups of sham mice as shown in Fig 16C-D. However, I did notice that the expression of PPAR- γ was reduced in sham CBS mice compared to sham WT mice and that GYY4137 supplementation could not mitigate this effect. The observed reduction of PPAR- γ mRNA level in sham CBS mice,

compared to sham WT mice, was not statistically significant ($p=0.7423$). Similarly, I did not observe any significant improvement in mRNA expression for PPAR- γ in sham CBS mice after GYY4237 treatment ($p=0.3549$) (Fig. 16D).

Figure 16A-B. Effect of GYY4137 on the improvement of angiogenic markers in skeletal muscle of post-FAL mice. (A) Western blot analysis is showing protein expressions: HIF1- α , VEGF, and PPAR- γ in the top panel and densitometric analysis of Western blot images are shown in the bottom panel, where mice number (n)=4 in individual group; (B) mRNA expression for HIF1- α , VEGF, and PPAR- γ (log transformed) in skeletal muscle of post-FAL mice, where mice number (n)=4 in individual group. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and statistical difference

*p<0.05 vs. WT and #p<0.05 vs. CBS (FAL=femoral artery ligation).

Figure 16C-D. Effect of GYY4137 on angiogenic markers in skeletal muscle in sham mice. (C) Western blot analysis is showing protein expressions: HIF1-α, VEGF, and PPAR-γ in the top panel and densitometric analysis of Western blot images are shown in the bottom panel, where mice number (n)=4 in individual group; (D) mRNA expression for HIF1-α, VEGF, and PPAR-γ (log transformed), where mice number (n)=4 in individual group. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m., statistical difference *p<0.05 vs. WT and #p<0.05 vs. CBS.

Finally, I measured the vessel density employing barium sulfate angiography

after 21 days of FAL surgery. It was noticed that total collateral vessel numbers were significantly less in the post-FAL CBS mice in comparison to post-FAL WT mice, this effect was further significantly improved upon GYY4137 treatment (Fig. 17A-B). Besides, blood flow in the hindlimb after 21 days of FAL was reduced considerably in CBS mice compared to WT mice, and it was improved by GYY4137 treatment as seen in Fig. 17C-D. Although I did not notice any difference in the mRNA expression levels of NOS3, I observed that the p-eNOS levels were reduced in the post-FAL CBS mice as compared to post-FAL WT mice, interestingly, this effect was improved via GYY4137 treatment (Fig. 17E). The changes in the plasma nitrite levels in experimental mice were also monitored as the marker of nitric oxide (NO) production. Although not statistically significant, my findings revealed a reduction of plasma nitrite levels in post-FAL CBS mice as compared to post-FAL WT mice ($p=0.1050$), and similarly, I noticed a trend of improvement of this effect with the GYY4137 administration ($p=0.2923$) (Fig. 17F).

Figure 17A-D. GYY4137 supplementation improves angiogenesis in the hindlimb muscle after 21 days of FAL in CBS^{+/-} mice. (A) Barium angiogram images showing vascular density in the hindlimb of skeletal muscle; (B) Quantitation of collateral vessel numbers in hindlimb post FAL mice, where mice number (n)=4 in individual group; (C) Blood flow rate measurements in hindlimb post FAL mice, where mice number (n)=4 in individual group; (D) Laser-Doppler perfusion imaging showing the intensity of limb perfusion 21 days post FAL mice. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and statistical difference *p<0.05 vs. WT and #p<0.05 vs. CBS. (FAL=femoral artery ligation).

Figure 17E-F. Effect of GYY4137 supplementation on eNOS-phosphorylation and plasma nitrite levels in experimental mice. (E) Western blot analysis of protein expressions: p-eNOS and eNOS in the top panel and densitometric analysis of p-eNOS/eNOS ratio from Western blot images are shown in the right panel, and mRNA expression of NOS3 is shown in bottom panel, where mice number (n)=4 in individual group; (F) Nitrite+Nitrate levels in plasma of post-FAL mice measured by Griess assay, where mice number (n)=4 in individual group; The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and statistical difference *p<0.05 vs. WT and #p<0.05 vs. CBS. (FAL=femoral artery ligation)

DISCUSSION

Earlier studies also showed that HHcy has a profound inhibitory effect on EC proliferation and their migration (269,270,335-337). In the present study, I examined whether HHcy condition could impair angiogenesis *in-vivo* during a chronic ischemic insult. Although there are many *in-vivo* models available to study angiogenesis, either by passing a flexible wire or by applying a laser or an electrical current, none of these are relevant to the clinical setting (338-340). In this study, I used the femoral artery ligation (FAL) model by employing a genetically engineered mouse model (CBS^{+/-}) mimicking HHcy conditions as seen in HHcy patients with CBS mutation to study the post-ischemic angiogenesis phenomenon during HHcy. My results showed that HHcy is associated with defective angiogenesis, and exogenous H₂S supplementation has a protective role in mitigating this effect.

Angiogenesis is a natural process during chronic regional ischemia, which requires EC proliferation, migration, differentiation, and survival to form new blood vessels in order to compensate for the hypoxic environment (341). VEGF is a prototypical angiogenic cytokine that plays a vital role in this process and has been widely studied (342-344). A previous report involving hindlimb ischemia in CBS^{+/-} mice showed no difference in VEGF levels 7 days of post-ischemia (345). However, they did notice a significant reduction in capillary density in the CBS mice compared to WT mice after 21 days of ischemia (345). Interestingly, my results demonstrate a significant decrease in PPAR- γ and VEGF expression after 21 days of FAL, suggesting that lower expressions of post-ischemic PPAR- γ may be responsible for delayed induction of VEGF in CBS mice compared to that of WT mice (323). I noticed that the exogenous administration of GYY4137 could improve blood flow and collateral vessel density in skeletal muscle of CBS^{+/-} mice (Fig. 17C).

H₂S has been studied extensively for its positive effects in the cardiovascular

system, demonstrating profound vasodilatation, vascular protection, homeostatic regulation of blood pressure and many others (54,57-59,61). A previous study using chicken chorioallantoic membrane model revealed that H₂S increased the length and complexity of the vascular network (270). Likewise, in this study, I noticed that exogenous supplementation of GYY4137 could improve collateral vessel density after 21 days of FAL in the CBS^{+/-} mice. Similar to this study, Moore and colleagues were able to show that intraperitoneal administration of NaHS induced neovascularization in an *in-vivo* mouse model using a Matrigel plug assay (269). A previous report showed that genetic deletion/silencing of CSE (another H₂S-producing enzyme) in the endothelium reduced migration and sprouting of ECs *in-vitro*, wherein VEGF played a critical mediator (270). In the present study, I observed that PPAR-γ and VEGF expressions were significantly downregulated in CBS mice compared to WT mice. I also demonstrated that these effects were mitigated via GYY4137 administration. This suggests that most likely VEGF is regulated via the PPAR-γ dependent pathway, further corroborating Biscetti, et al.'s findings wherein they clearly showed that activation of PPAR-γ led to endothelial tube formation and induction of VEGF in ECs (323). Similarly, other investigators revealed that inhibiting PDE activity by H₂S induces PPAR-γ protein and mRNA expressions (331).

NO is also an endogenous gasotransmitter that, like H₂S, is involved in vasorelaxation and stimulation of angiogenesis (346,347). HHcy was also found to quench NO (a vasodilator) by the formation of peroxynitrite anion (ONOO⁻) and uncoupling of eNOS, further reducing the bioavailability of NO (348-350). Similarly, I noticed nitrite levels and phosphorylation of eNOS were found to be reduced in CBS mice in comparison to WT mice. eNOS is known to produce NO during angiogenesis via VEGF axis (328); thus, it appears that impaired angiogenesis in HHcy could be due to the reduction of NO bioavailability. In this work, I demonstrated that nitrite levels and

eNOS activation were reduced in the CBS^{+/-} mice compared to WT mice, and their levels could be recovered via GYY4137 treatment. These findings are also highly consistent with previous reports where H₂S was shown to stimulate Akt in endothelial cells, leading to the induction of eNOS through phosphorylation of Ser1177 (activation site) and parallel dephosphorylation of Thr495 (inhibitory site) (351,352).

In conclusion, my work embodies the pro-angiogenic role of the H₂S molecule during HHcy condition. I opine that additional pathways might be at work during angiogenesis (97); however, further investigation needs to be undertaken involving similar but not identical scenarios wherein muscle myopathy is the outcome of metabolic abnormalities. In brief, H₂S does hold potential ramifications towards developing it as a clinically relevant therapeutic option for chronic conditions that are implicated in a host of inflammatory and cellular stress injury, including the apparent defect in angiogenesis (97).

CHAPTER V

HYDROGEN SULFIDE MITIGATES HHcy-MEDIATED SKELETAL MUSCLE
ATROPHY VIA JNK/FOXO1 AXIS

Introduction

Homocysteine (Hcy), a sulfur-containing non-protein amino acid is generated via one-carbon metabolism in the methionine cycle. Dietary methionine is first converted to S-adenosyl methionine (SAM) and then to S-adenosyl homocysteine (SAH) in methionine cycle. SAH is further converted to Hcy which is remethylated to methionine via folate cycle and the cycle continues (353). Under conditions of low cysteine or saturation of Hcy remethylation, Hcy is further metabolized by the transsulfuration pathway to cysteine (2). In the rate-limiting step of the transsulfuration pathway, Hcy is first converted to cystathionine through cystathionine β -synthase (CBS) where Vitamin B6 (pyridoxine) is an essential co-factor (7). Cystathionine is further transformed to cysteine by cystathionine γ -lyase (CSE), which further generate GSH. The normal range of plasma Hcy levels for young adults (0-30 years) is 4.6 - 8.1 μ M and for older adults (30 years and above) is 4 -15 μ M (354). In healthy individuals, the generation and elimination of Hcy remain at equilibrium. However, during hyperhomocysteinemia (HHcy), the plasma Hcy levels tend to increase (moderate HHcy: 15-30 μ M, intermediate HHcy: 30–100 μ M, and severe HHcy: >100 μ M) (7,355). Mutations in the CBS gene causes Hcy accumulation in the blood circulation due to disruption of the transsulfuration pathway (356).

Skeletal muscular atrophy is a pathophysiological condition that arises due to HHcy (357). It causes loss of skeletal muscle mass, leading to muscle weakness, inactivity, and increased mortality (5,15,20,21,46,66,82). The molecular mechanism attributed to muscle atrophy is the upregulation of ubiquitin ligases like RING-finger protein-1 (MURF-1) and muscle atrophy F-box (MAFBx), also known as Atrogin-1, which initiates the degradation of muscular proteins and eventually cell death and muscle mass reduction (358,359). Indeed, several E3 ubiquitin ligases, such as muscle MuRF1, MAFBx, Nedd4.1, TRAF6, and MUSA1, have been identified which mediate degradation of both thick and thin filaments during skeletal muscle atrophy (214,215). Therefore, identification of the precise molecular mechanism(s) as to how these E3 ubiquitin ligases are regulated during HHcy is essential to devise future preventive strategies.

Forkhead Box (FOX) proteins are a group of transcription factors with a conserved DNA binding domain and are responsible for regulating a number of E3-ubiquitin ligases upon a variety of cellular stress responses (216-219). Previous studies showed that growth factor-activated protein kinase B (Akt) and stress-activated c-Jun N-terminal kinase (JNK) have opposing effects on FOX class O (FOXO) (common in mammals): Akt inhibits FOXO activity via preventing its nuclear localization, whereas JNK increases FOXO activity by promoting its import in the nucleus (216,220-223). FOXO1 and 3 are widely expressed across all tissues, FOXO4 is primarily expressed in muscle and kidney tissues, and FOXO6 is expressed in developing brain and liver tissues (360). Post-translational modifications of FOXOs determine its regulation and therefore, its cellular localization (216). FOXO1 has been shown to be the primary transcription factor regulating MuRF1 and Atrogin-1, these two proteins were reported to be highly upregulated during skeletal muscular atrophy (224).

CBS and CSE are the vital enzymes generating H₂S from Hcy via the transsulfuration pathway (330). H₂S is increasingly being recognized as an important

signaling molecule in the cardiovascular and nervous systems because of its ability to neutralize a variety of ROS moieties (63,236,329). In fact, patients with a dysregulated Hcy metabolism due to CBS deficiency are likely to be more prone to oxidative stress-mediated damages (361,362). Hence, the purpose of this study was to analyze whether Hcy instigates muscle atrophy via upregulation of E3 ubiquitin ligases like MURF-1 and Atrogin-1 through JNK/FOXO1 axis and H₂S attenuates these effects. My results suggest that HHcy can induce muscle atrophy via upregulation of Atrogin-1 and MuRF1, whereas H₂S could be used as a therapeutic option to restore physiological homeostasis in skeletal muscle during HHcy condition.

Materials and methods

Animal maintenance and diet protocol. Male wild-type (WT, C57BL/6J) and CBS^{+/-} (B6.129P2-Cbstm1Unc/J 002853) mice were purchased from the Jackson Laboratory (Bar Harbor, ME, USA) (71). All animals were ~8-12 weeks-old and maintained in 12:12 h light–dark cycle with regular mouse chow diet in the animal facility of the University of Louisville. All animal protocols and care were carried out according to the guidelines of National Institute of Health (NIH Pub. No. 86–23, revised 1985) and were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of Louisville (KY, USA). Animals were divided into 4 experimental groups: (1) Wild-type C57BJ/L6 mice (WT), (2) CBS^{+/-}-heterozygous mice fed with methionine (CBS+Met) (3) NaHS-supplemented wild-type mice (WT+NaHS), and (4) NaHS-supplemented CBS^{+/-}+Met (CBS+Met+NaHS). Mice were treated with NaHS for 8 weeks (30µM/kg/day, I.P.) and fed with a methionine-enriched and low-folate, low-Vitamin B6, low-B12 diet (Cat. No. TD 97345; Harlan Teklad, Madison, WI, USA) (301-304), while the WT mice were given 0.9% normal saline (vehicle control)

and fed with normal chow (Purina Farmer's Exchange, Framingham, MA, USA).

Body weights and physical activity monitoring and tissue collection. Body weights were measured at 0 week, 4 weeks and after 8 weeks intervals during NaHS treatment (Table 4, Appendix I). Further, the animals were routinely inspected for discomfort, body posture, skin integrity (injury), and fur appearance to monitor their physical activity. At the end of the experiment, animals were euthanized by using 2X tribromoethanol (TBE), and both blood and muscle samples were collected for further analysis.

Genotype analysis of the heterozygous CBS^{+/-} mouse. After purchasing, mice were cross-bred, yielding around 10 % CBS^{-/-}, 60 % CBS^{+/-}, and 25 % CBS^{+/+}. For genotyping, tail samples were collected, and genotypic analysis was performed using PCR by targeted disruption of the CBS gene at loci, as shown in Fig. 18A. The PCR products were run on 1.2 % agarose gel (prepared in TAE buffer, pH 8.4) in the presence of ethidium bromide and the images recorded in a gel documentation system (305). CBS^{+/-} heterozygote gene-positive mice produced two bands (450 and 308 bp), while CBS^{+/+} mice represented only one band (308 bp).

Cell culture and treatments. C2C12 cells (immortalized mouse myoblast cell line, ATCC) were cultured in Corning® T-75 flasks in ATCC-formulated DMEM supplemented with 10% Fetal Bovine Serum (FBS), 0.1% penicillin and streptomycin (P/S) at 37 °C with 5% CO₂. The C2C12 cells were grown to 80% confluence and were plated for 4 different experimental groups: Group 1: CT (PBS as vehicle control); Group 2: Hcy (500µM); Group 3: Hcy+NaHS (250 µM) and Group 4: NaHS. In this study, we used 1mM Hcy and 250µM NaHS concentrations for the individual treatments (20,246). A stock solution of Hcy, NaHS were prepared by directly dissolving in basal DMEM medium (serum-free media). Following 24 h of treatment as mentioned earlier, cells were processed for further biochemical analysis.

Reagents and antibodies. Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS) were purchased from American Type Culture Collection (Manassas, VA, USA) and trypsin EDTA was from VWR (Radnor, PA, USA). ECL reagent and polyvinylidenedifluoride (PVDF) membrane were from Bio-Rad (Hercules, CA, USA). All other reagents and chemicals were ordered from Sigma–Aldrich or available highest grade.

Primary antibodies for Western blot analysis: rabbit anti-FOXO1A (1:1000, Abcam, Cat # ab12161), rabbit anti-p-FOXO1A (Thr24) (1:1000, Millipore, Cat #2599), mouse anti-GAPDH (1:10000, Millipore, Cat # MAB374). Atrogin-1 (1:1000, Abcam Cat # ab92281), myosin heavy chain-I (MHC-I) (1:1000, Abcam Cat # ab11083), MuRF-1 (1:1000, Abcam Cat # ab172479) and Laminin (1:1000, Abcam Cat # ab11575).

Secondary antibodies for Western Blot Analysis: mouse anti-rabbit (1:2000), rabbit anti-mouse (1:2000) were ordered from Santa Cruz Biotechnology (Dallas, TX, USA). Alexa Fluor 488 donkey anti-mouse (Cat # R37114), Alexa Fluor 488 donkey anti-rabbit IgG (H+L) (1:1000, Cat # A21206), Alexa Fluor 546 donkey anti-mouse IgG (H+L) (1:1000, Cat # A10036), Alexa Fluor 546 donkey anti-rabbit IgG (H+L) (1:1000, Cat # A10040) were ordered from Invitrogen (Eugene, OR, USA)

Immunocytochemistry (ICC). For ICC, C2C12 cells were grown in chamber slides (Lab-Tek II) and treated as mentioned above. After 24 h of treatment, cells were washed 2 times with 1X phosphate buffer saline (PBS) and fixed with 4% paraformaldehyde (PFA) diluted in 1X PBS for 10 minutes at room temperature. The cells were permeabilized and blocked at the same time with a solution of 2 % bovine serum albumin (BSA) and 0.5 % Triton X-100 in 1X PBS for 30 minutes at room temperature. The cells incubated with primary antibodies diluted in 0.1% BSA and 0.5 % Triton X-100 in 1X PBS at the concentrations as mentioned above and kept for overnight at 4°C. The next day the cells were washed 3 times with 1X PBS and then incubated with secondary antibody using

the concentrations as mentioned above for 1 h at room temperature. After washing the cells 5 times with 1X PBS after secondary antibody incubation, they were mounted with mounting media containing DAPI (Vectashield Cat # H-1200) and viewed under the confocal microscope (Olympus FluoView1000, Pittsburgh, PA, USA).

Immunohistochemistry (IHC). For IHC, I used cryo-tissue sections of the gastrocnemius muscle (7 μ m) which were labeled for immunofluorescence following the standard protocol. Briefly, first, the tissue sections were fixed in 4% paraformaldehyde and permeabilized with 0.25% Triton X-100 in PBS. Then, the sections were incubated overnight in primary antibodies at 4 °C, and after that, secondary antibodies labeled with either Alexa Fluor-488 or 594 (Invitrogen) appropriate to the primary antibody species were applied. Sections were cover-slipped with ProLong™ Gold Antifade Mountant. Stained images were visualized and analyzed for fluorescence intensity under an EVOS™ FL Auto Imaging System (Thermo Fisher Scientific, Waltham, MA, USA) using an appropriate filter. To study the cross-sectional area in the gastrocnemius muscle from each group, I analyzed 30-40 fields/mouse.

Western blot analysis. First, the cells or tissues were mixed with cold RIPA lysis buffer with protease inhibitor cocktail, phenylmethylsulfonyl fluoride (PMSF) and phosphatase inhibitor (sodium orthovanadate) and then sonicated employing the Sonifier 450 (Branson Ultrasonics, Danbury, CT, USA) using 3 x 5 sec at setting "3". After that the suspensions were centrifugated at 17,400 x g for 20 minutes at 4°C. The supernatants were collected in fresh tubes and were stored at -80°C until further use. Protein concentration was determined using Bradford assay to ensure that the proteins were loaded in equal concentrations. Protein lysates were subjected to 8-12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in a tris-glycine-SDS buffer for proper protein separation and transferred on a polyvinylidene difluoride (PVDF) membrane electrophoretically overnight at 4°C. The membrane was first blocked using

5% milk in 1X tris-buffer saline and Tween 20 (TBS-T) for 1 hr at 4°C and then incubated with the primary antibodies at the concentrations as mentioned above for overnight at 4°C. After primary antibody incubation, the membranes were washed 3 times with 1X TBS-T followed by incubation with secondary antibody conjugated with HRP for 1 hr at room temperature. Membranes were again washed 3 times with TBS-T, then developed using ECL Luminata Forte reagent (Millipore, Temecula, CA, USA) and imaged using a Chemidoc (Bio-Rad, Hercules, California, USA). Band intensity was determined using densitometry analysis using Image Lab™ Software (Bio-Rad, Hercules, CA, USA).

Total Homocysteine measurement. The total tHcy levels were measured from plasma of experimental mice using homocysteine assay kit (Crystal Chem, IL, USA) as per manufacturer's instructions.

Muscle fatigability tests. Muscle fatigability test was developed from recommendations listed in the *Resource Book for the Design of Animal Exercise Protocols* by the American Physiological Society (APS) with minor modifications. First, one mouse at a time was allowed to swim for 10 mins across 4 different days for acclimatization to the environment. I used a swimming tub with water temperature usually between 32-36°C. The depth of water was maintained at a minimum of 30cm so that mice couldn't touch the bottom with 10–15cm distance left from the top to prevent animals from climbing or jumping out. On the final day, each mouse was placed in the water to swim to check their maximum swimming capacity (Table 5, Appendix I). To monitor their live motion, I used Clever Systems (Reston, VA, USA) in the previously discussed method (46). If the mice discontinue swimming for 2 secs, they were gently nudged to promote their movement, and if they were drowning in the water, then they were immediately taken out as per protocol.

To determine muscle grip strength of experimental mice, I used Rotarod instrument (San Diego Instruments, San Diego, CA, USA) and Grip strength test meter

(Bioseb, Pinellas Park, FL, USA) (364,365). Briefly, Rotarod performance was done by placing them on the rotarod and allowing them to run at a constant low speed (12 RPM) for 5 mins across 4 different days (acclimatization steps). Following acclimatization, on the final day mice were placed on the rotarod (12 RPM) and allow to run until they fall off from the apparatus (time was recorded) (Table 5, Appendix I). The grip strength of both forelimbs and hindlimbs were measured by using a grip strength meter. Each mouse was held by the base of the tail and placed in front of the grasping grid. Once the mouse grasped the grid, it was slowly pulled back until the pulling force overcame the mouse's grip strength. This process was repeated 5 times for each mouse with 15 mins gap between each repeat and all measurements of grip strength/body weights were recorded (Table 5, Appendix I).

Statistical analysis. All values were expressed as mean $\pm$ s.e.m. One-way or two-way ANOVA was conducted for the statistical analyses for the different treatment groups using GraphPad Prism (Ver. 7) software. For all *in-vivo* experiments mice number (n)= 4-5, in each group, and for all exercise capacity test, (n)=9-11 mice were used in each group. The significance threshold was set at $p < 0.05$. A minimum of 3 technical replicates were conducted for each protein expression analysis and ICC experiment.

Results

HHcy causes skeletal muscle atrophy in CBS+Met mice. In this study, I noticed CBS+Met mice had significantly low body weights most likely because of excessive muscle wasting in comparison to WT mice (Fig. 18A and 18B). Although I didn't observe any changes in tibial length between each group of experimental mice, gastrocnemius and quadriceps muscles weights were significantly reduced in CBS+Met compared to WT mice (Fig. 18C and 18D). Although not significant, I did notice a reduction of tibialis anterior (TA), extensor digitorum longus (EDL) and soleus muscles weights in CBS+Met

mice compared to WT mice. After administration of NaHS for 8 weeks, I noticed an improvement in overall body weights and muscle mass as shown in Fig. 18C and 18E. I also noticed tHcy levels in plasma were significantly increased in CBS+Met than WT mice and was similar in NaHS treated CBS+Met mice (Fig. 18F).

Figure 18: Genotypic and phenotypic characteristics of experimental mice groups. (A) Genotyping of CBS+/- and WT mice; (B) morphological difference of skeletal muscle in hindlimbs between CBS+Met and WT mice; (C) difference in various muscle weights such as gastrocnemius (gastroc), quadriceps (Quad), tibialis anterior (TA), extensor digitorum longus (EDL) and soleus, where mice number (n)=4 in individual group; (D) Tibia length measurements, where mice number (n)=4 in individual group; (E) Body weight measurements, where mice number (n)=4 in individual group; (F) total homocysteine (tHcy) measurements, where mice number (n)=4 in individual group. The

overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and statistical difference * $p < 0.05$ vs. WT and # $p < 0.05$ vs. CBS+Met.

NaHS treatment improves muscle fatigability in CBS+Met mice. To measure HHcy effect on muscle fatigability, I performed swimming capacity test for all experimental groups. I noticed that CBS+Met mice moved less distance and spent less time in swimming, whereas NaHS supplementation improved their capacities significantly (Fig. 19A and 19B). Similar findings were also observed for the muscle grip strength test as shown by less latency to fall from rotarod and grip strength/BW in CBS+Met as compared to WT mice. After 8 weeks of NaHS administration, these effects were substantially improved in CBS+Met mice (Fig. 19C and 19D).

Figure 19: NaHS treatment improves muscle fatigability in CBS+Met mice compared to WT mice. (A) Measurements of muscle fatigability was done by swimming test, in the left side shows total distance moved and on the right side shows total time spent during the swimming performance test; (B) Images captured during live recording of swim test (top), representative animal tracings were shown after motion performance in swimming test for each group (bottom); (C) Images showing results of grip strength using rotarod performance test (left) and grip strength test (right). (D) Images captured in rotarod (top) and Bioseb grip strength meter (bottom) during grip strength test. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m. and mice number (n)=9 mice and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

HHcy induced morphological changes in skeletal muscle in-vivo. To understand the effect of HHcy on morphological changes in the muscle fibers, I analyzed the cross-sectional areas (CSAs) by laminin staining. Results of the staining showed a significant reduction of CSAs in gastrocnemius muscle fibers isolated from CBS+Met in comparison to WT mice (Figure 20A and 20B). Although not statistically significant, I observed an improvement of CSAs of skeletal muscle fibers in CBS+Met mice after NaHS treatment for 8 weeks.

Figure 20: HHcy reduces cross-sectional areas (CSAs) of skeletal muscle fibers in CBS+Met mice compared to WT mice. (A) Laminin staining showing cross-sectional areas (CSAs) measurements are low in GA muscle of CBS+Met mice compared to WT mice (Bar=200µm); (B) Quantification of CSAs from laminin staining images are shown on the right. To study the CSAs of the gastrocnemius muscle fiber from each group, I analyzed 30-40 fields/mouse. Representative image from each group of mice is shown here. The overall difference between the experimental groups was determined by one-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and mice number (n)=4 and *p<0.05 vs. WT.

To check whether HHcy induces fibrosis in skeletal muscle fibers, I performed H&E and Masson trichrome staining in muscle CSAs of gastrocnemius muscle. Results revealed a higher level of fibrosis and collagen deposition in muscle CSAs derived from CBS+Met as compared to WT mice. Interestingly, treatment with NaHS for 8 weeks was found to alleviate these effects in CBS+Met mice (Fig 21A-21C).

Figure 21: HHcy-induced fibrosis and collagen deposition in skeletal muscle *in-vivo*. (D) H&E staining in cross sectional areas of gastrocnemius muscle showing morphological differences of muscle fibers between CBS+Met and WT mice, images are taken using EVOS® FL Auto Cell Imaging System where mice number (n)=4. (Bar=400µm), Representative areas from H&E staining images are zoomed in to show more clear view; (E) Quantification of regenerated muscle fibers as quantified by centrally located nuclei from H&E staining images; (F) Masson's Trichrome staining in cross sectional areas

(CSAs) of gastrocnemius muscle showing blue color stain (white arrowheads) as collagen deposition in the muscle of CBS+Met mice compared to WT mice. Images are taken using EVOS® FL Auto Cell Imaging System where mice number (n)=4-5. (Bar=400µm); (G) Quantification of collagen deposition as quantified by blue color stain from Masson's Trichrome staining images. The overall difference between the experimental groups was determined by one-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and mice number (n)=4-5 and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

Effect of Hcy on Akt-phosphorylation, and subcellular localization of FOXO1. To study the effect of HHcy on Akt-phosphorylation, I did Western blots analysis; the results showed that Hcy treatment significantly reduced Akt-phosphorylation in C2C12 cells as compared to vehicle controls, whereas this effect was successfully mitigated via NaHS administration (Fig. 22A).

As I noticed Akt-phosphorylation is downregulated and JNK-phosphorylation is upregulated after Hcy treatment in C2C12 cells (Figure 22A and 12), I tested the subcellular localization of FOXO1 using ICC analysis. My confocal images showed that p-FOXO1 is primarily localized in the nucleus and FOXO1 is primarily expressed in the cytoplasm in the cells across all the treatment groups (Fig. 22B). However, I observed that the pFOXO1/FOXO1 ratio is high for Hcy treated C2C12 cells compared to controls and this effect was reversed via NaHS supplementation (Fig. 22B).

Figure 22: Hcy attenuates Akt-phosphorylation and induced nuclear localization of p-FOXO1 in C2C12 cells. (A) Western blots analysis showing Hcy treatment reduced Akt-phosphorylation, whereas NaHS treatment mitigates this effect. Densitometric measurement of Akt-phosphorylation from above Western blots image is shown on the right, where n=3 technical replicates; (B) Representative images showing intracellular localization of p-FOXO1 and FOXO1 in the left. The p-FOXO1/FOXO1 ratio based on fluorescent intensity from ICC images are shown on the right, where n=3 technical replicates. Cells were observed and imaged under the confocal microscope at 100X magnification. Quantification of fluorescent intensity were shown on the right. The overall difference between the experimental groups was determined by one-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean $\pm$ s.e.m., and *p<0.05 vs. CT and #p<0.05 vs. Hcy.

Hcy enhanced Atrogin-1 and MuRF-1 expression in the skeletal muscle. I noticed the expression of Atrogin-1 and MuRF-1 were higher in Hcy treated C2C12 cells in comparison to vehicle controls, and this effect was attenuated by NaHS treatment (Fig. 23A). Similar findings were observed in muscle collected from experimental mice (Fig. 23B). In addition, IHC experiments confirmed higher MuRF-1 and reduced myosin heavy chain type-I (MHC-I) expression in skeletal muscle of CBS+Met mice as compared to WT mice, and this effect was alleviated by NaHS treatment (Fig. 24A-C). The Western blot results also confirmed a similar association as seen in IHC staining (Figure 24D and E).

Figure 23. Hcy enhanced Atrogin-1 and MuRF-1 expressions in the skeletal muscle. (A) Western blots data showing expression of Atrogin-1 and MuRF-1 were elevated in C2C12 cells after Hcy treatment compared to controls. Densitometric measurements of Atrogin-1 and MuRF-1 expression from above Western blots images are shown on the

bottom, where n=3 technical replicates. Data are shown as mean±s.e.m., where n=3-4 biological replicates and *p<0.05 vs. CT and #p<0.05 vs. Hcy. (B) Western blots data showing expression of Atrogin-1 and MuRF-1 were elevated in the muscle of CBS+Met mice compared to WT mice. (H) Densitometric measurement of Atrogin-1 and MuRF-1 expression from above Western blots images is shown on the bottom, and where mice number (n)=4. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

Figure 24. High Hcy mediates elevated expression of MuRF1 and degradation of its targets protein MHC-1 in skeletal muscle of CBS mice compared of WT mice. (A)

Immunohistochemistry analysis showing representative images of elevated expression of MuRF1 and reduced expression of MHC-I in tissue cross-section of the GA muscle in CBS+Met mice compared to WT mice. The arrows indicate the respective expression levels of MuRF-1 (low) and MHC-1 (high) in the fiber content of the GA muscle (Bar=200µm). (B) Quantification of MHC-1 expression from IHC images is shown on the right and where mice number (n)=4. (C) Quantification of MuRF-1 expression from IHC images is shown on the right, and where mice number (n)=4. (D) Western blots data showing protein expression of MHC-1 and MuRF-1 in the muscle of CBS+Met mice compared to WT mice. (E) Densitometric measurement of MHC-I and MuRF-1 from above Western blots images is shown on the right, and where mice number (n)=4. The overall difference between the experimental groups was determined by one-way or two-way ANOVA, and a Tukey's post hoc analysis was run when overall statistically significant difference occurred in group means. Data are shown as mean±s.e.m. and *p<0.05 vs. WT and #p<0.05 vs. CBS+Met.

Discussion

Skeletal muscle is the largest organ in the human body and makes up almost 40% of the body's weight (351). Muscle atrophy can occur due to result in the reduction of muscle mass, structural, and metabolic alteration of intrinsic muscle cells (138). Although HHcy was reported to cause muscle atrophy, the precise molecular mechanism of this effect was not identified before. In this study, I observed a reduction of body weights in HHcy mice (genetically engineered heterozygous CBS deficient mice) compared to age matched WT mice (Fig. 18E). As I also noticed their tibia lengths were similar with WT mice and muscle masses in hindlimb were lower in comparison to WT mice (Fig. 18C), suggesting that overall reduction of body weight may be at least partly due to the reduction of muscle mass (351). The muscle fiber is bound to connective

tissues, nervous tissues and blood vessels for oxygen and nutrient supply (366,367), so reduction of muscle mass may impair its functional capabilities. Indeed, I noticed that CBS mice have significantly poor performance in swimming and grip strength test compared to WT mice (Fig. 19). Interestingly, I also identified that NaHS administration could successfully mitigate these effects. The basic unit of the muscle is the muscle fiber, so any structural or morphological changes in muscle fiber can play havoc with its functional capabilities (368). Muscle atrophy is most often associated with fibrosis in muscle fibers, excessive accumulation of extracellular matrix (ECM) components, particularly collagen (369). This study showed that HHcy could actually significantly reduce CSAs, and induce fibrosis and collagen deposition in muscle fibers of CBS mice compared to WT mice and these effects of HHcy were improved upon NaHS administration (Fig. 20 and 21). This study is similar to previous study by Kanwar et al. [1976] found that HHcy can cause focal fragmentation, disruption and smearing of the Z-discs, increased collagen deposition in the basal lamina and disorganization of the myofilaments in the skeletal muscles (14)

To further characterize underlying molecular changes of HHcy-mediated muscle atrophy, I analyzed intracellular localization of p-FOXO1 and FOXO1 by ICC experiment. Regulation of the subcellular localization of FOXO1 is critical to its transcriptional activity (354-356). My findings provide a new insight into the molecular background of the effect of HHcy in induced nuclear translocation of p-FOXO1. I observed induction of p-FOXO1 expression and its nuclear localization upon treatment with Hcy and mitigated upon NaHS treatment (Fig. 22) led us to conclude that possibly Hcy stabilizes FOXO1 in the nucleus and thus allows it to carry on its transcriptional activity. Recent studies indicate that JNK is responsible for FOXO activation under stress conditions (357,358). As I also found high Hcy can activate JNK (chapter IV, Fig. 12), suggesting that JNK may also play a role in regulating nuclear stabilization of FOXO1. When FOXO1 is

phosphorylated through Akt on S²⁵⁶, it creates a 14-3-3 binding site (370), that masks the nuclear localization signal (NLS) and prevents nuclear translocation, thereby inhibiting the activities of FOXO1 (371-373). However, during HHcy condition, Akt is downregulated, hence in addition to JNK pathway, reduced Akt-phosphorylation in C2C12 cells after Hcy treatment can stabilize FOXO1 inside the nucleus thus allowing them to carry their transcriptional activity (374,375).

Previous results suggested the role of FOXO1 transcription factors in the regulation of E3-ubiquitin ligases like Atrogin-1, and MuRF1 (376-379). Similarly, my findings suggested that expression of both MuRF1 and Atrogin-1 were upregulated in both *in-vitro* and *in-vivo* models and NaHS administration mitigated these effects. Together these results suggest that upregulation of these E3 ubiquitin ligases may be mediated through the FOXO1 transcription factors, which were found to be involved in most forms of atrophy (377,380-384). The overall results from this study demonstrate that HHcy-mediated oxidative/ER-stress upregulates MuRF1 and Atrogin-1 expression through JNK-dependent FOXO1 activation, which may degrade some vital proteins in muscle, such as MHC-I and MyoD (385,386). Indeed, I noticed that expression of MHC-I was decreased in skeletal muscle of CBS+Met mice (Fig. 24), which indicates that higher expression of MuRF-1 could trigger muscle atrophy via proteasomal degradation of its target proteins such as MHC-I (387).

In conclusion, I have elucidated a well-defined signaling pathway for the upregulation of E3 ubiquitin ligases in HHcy-mediated skeletal muscle atrophy through activation of FOXO1 via JNK phosphorylation. I have also provided important data regarding potential mechanistic role H₂S in mitigation of HHcy-mediated skeletal muscle atrophy. This study indicates that H₂S could be developed as a potential therapeutic target in various forms of musculopathies wherein HHcy is linked with metabolic dysfunction.

CHAPTER VI

SUMMARY

HHcy is a well-accepted risk factor for vascular diseases (136), and several studies reported that HHcy conditions lead to skeletal muscle weakness and functional impairment (14,19,20). Results from the present study demonstrate that HHcy due to CBS^{+/-} deficiency displays decreased bodyweight, angiogenesis and skeletal muscle mass, which ultimately lead to muscle myopathy. This is similar to neurological disorders such as amyotrophic lateral sclerosis (ALS), and multiple sclerosis, causing muscle degeneration and are also associated with HHcy (15). My dissertation elucidates the potential molecular mechanisms as to how HHcy mediates skeletal muscle myopathy via induction of oxidative and ER-stress responses, apoptosis, atrophy and reduction of angiogenesis (Fig. 25). This study also identified the apparent beneficial effects of H₂S on mitigation of HHcy effects on skeletal muscle dysfunction.

In chapter IV, I explored that high Hcy can induce intracellular oxidative and ER-stress responses in skeletal muscle. Interestingly, I found that these cellular stress responses were successfully mitigated via NaHS intervention. Moreover, I found that HHcy induced JNK phosphorylation in both *in-vitro* and *in-vivo* models, however, I did notice that NaHS could not mitigate JNK-phosphorylation in the *in-vitro* model, but it could reduce JNK-phosphorylation in the *in-vivo* model. To my best knowledge, the possible explanation for this observed difference is in the *in-vitro* settings, I only studied a single readout (24 h post-HHcy), unlike the *in-vivo* CBS^{+/-} model wherein I was able to

observe the continuous or prolonged effect of the NaHS mediated phospho-JNK status. Previous studies have revealed that JNK-phosphorylation was able to activate c-Jun which further regulated the expression of several pro-inflammatory and proapoptotic genes (283-291). Indeed, my data showed that the apoptosis rate was induced after Hcy treatment in C2C12 cells and it was mitigated by the NaHS supplementation. Furthermore, I found inflammatory cytokines IL-6 and TNF- α were higher in plasma from CBS^{+/-} as compared to wild-type mice; however, this effect was not mitigated via NaHS administration. The overall results from this chapter established the molecular mechanisms of the pathophysiological effects of HHcy in skeletal muscle myopathy via inducing cellular stress responses.

In chapter V, I elucidated that HHcy can inhibit angiogenesis via PPAR γ /VEGF axis in a hindlimb ischemia model. This study showed that HHcy reduced the HIF1 α , VEGF and p-eNOS levels in skeletal muscle after 21 days of chronic ischemia (generated via femoral artery ligation; FAL) in CBS^{+/-} mice compared to WT mice. Additionally, I also noticed that plasma nitrite levels were low in CBS^{+/-} mice in comparison to WT mice after 21 days of ischemia, suggesting that HHcy may reduce the bioavailability of NO during angiogenesis in CBS^{+/-} mice compared to WT mice. Interestingly, I also observed GYY4137 (another donor of H₂S) supplementation mitigates this HHcy effect in CBS^{+/-} mice. Furthermore, I identified the collateral vessel densities, and blood flow rates were lower in the hindlimb of CBS^{+/-} mice after 21 days of ischemia compared to WT mice, and these effects were also attenuated via GYY4137 treatment, suggesting that exogenous supplementation of GYY4137 can improve HHcy-mediated angiogenic defects. PPAR- γ is known to regulate angiogenesis via upregulation of VEGF levels (315), and VEGF can further activate eNOS during angiogenesis (320). Similar to the previous work this study showed that H₂S could

induce PPAR- γ expression (323), which suggest that H₂S may improve angiogenesis during chronic HHcy condition via PPAR- γ /VEGF axis.

In chapter VI, I demonstrated the beneficial effect of H₂S in the mitigation of HHcy-mediated skeletal muscle atrophy via JNK/FOXO axis. I found a reduction of body weights in CBS^{+/-} mice compared to age-matched WT mice and since their tibia lengths were similar, thus this effect may partly be due to the reduction of muscle mass. Then, to study whether this reduction of muscle mass can impair muscle function, I did whole animal muscle fatigability tests (by swim performance and grip strength test). The findings showed that HHcy induced muscle fatigability in CBS^{+/-} mice compared to WT mice and it was noticed that NaHS supplementation for 8 weeks was able to improve this effect. I also demonstrated that HHcy induced fibrosis, collagen deposition and reduced CSAs of skeletal muscle fibers in the gastrocnemius muscle of CBS^{+/-} mice compared to WT mice; interestingly NaHS supplementation improved this condition. I elucidated that actually HHcy induced muscle atrophy through upregulation of MuRF-1 and Atrogin-1 expressions via JNK/FOXO1 axis. Previous studies showed that Akt inhibits FOXO1 activity via preventing its nuclear localization, whereas JNK increases FOXO1 activity by promoting its import into the nucleus (352,356-359). This study showed that Akt-phosphorylation was attenuated, and JNK-phosphorylation was induced after Hcy treatment in C2C12 cells compared to vehicle controls, which possibly stabilizes FOXO1 in the nucleus and allows it to promote the expression of Atrogin-1 and MuRF-1 (E3 ubiquitin ligases). Whereas the upregulation of MuRF1 and Atrogin-1 due to HHcy condition may degrade their target proteins in the muscle fibers as reported previously for being responsible for muscle atrophy (361). Indeed, in this study, I noticed that upregulation of MuRF-1 degraded MHC-1 in CBS^{+/-} mice compared to WT mice and this effect was substantially mitigated via NaHS treatment for 8 weeks.

The overall results from this study demonstrated that HHcy can cause skeletal

muscle myopathy via cellular stress responses, apoptosis, inflammation, atrophy, and poor angiogenesis and identified a novel mechanism as to how H₂S could mitigate these effects.

Figure 25. Proposed model. Based upon the above findings, I have proposed a model that I firmly believe to be involved in HHcy-mediated skeletal muscle dysfunction.

However, there is still a lot more left to clarify in this regard, such as (i) people develop HHcy due to many reasons; mutation of the CBS^{+/-} gene is one of them. I studied the effects of HHcy on skeletal muscle using CBS^{+/-} mouse model that is similar to the physiological conditions but not identical as observed in HHcy patients, so a suitable animal model is still lacking. The half-life of NaHS is short, therefore most of the effects of H₂S vary in different studies. Moreover, delivery methods of H₂S donors (NaHS, Na₂S, GYY4137, etc.) are also a crucial factor because of changes in the pharmacokinetics and pharmacodynamics of these compounds. Also, there is a lot of hurdles to overcome with regard to identifying a proper delivery method for H₂S. Skeletal

muscle dysfunction ranges from general muscle weakness and soreness to severe myopathy, muscle wasting and cachexia. Some of the complex dysfunctions do not necessarily originate from skeletal muscle and there are many variables and signaling pathways that need to be determined for devising the strategies to alleviate these pathological effects of HHcy on skeletal muscle myopathy. Although many studies have been devoted to clarifying the molecular mechanisms involved in E-C coupling (excitation-contraction coupling) during skeletal muscle atrophy this was not assessed in my study due to limited resources and complexity associated with testing under *in-vivo* settings. I analyzed the FOXO1A localization via ICC experiment, however, I didn't confirm my findings via western blot analysis using fractioned samples (nuclear and cytoplasmic extracts); (vi) Finally, from this study it is not still confirmed whether H₂S is working via oxidative stress mechanisms or something else and whether other antioxidants (like N-acetylcysteine) has similar effects like H₂S. So, future work should address these questions to devise potential therapeutic options.

In brief, this work provides evidence that H₂S is beneficial towards mitigating the HHcy-mediated skeletal injuries incited by oxidative/ER-stress responses. The findings from my study suggest that HHcy can inhibit angiogenesis via antagonizing the angiogenic signal pathways encompassing the PPAR- γ /VEGF axis, and H₂S might be employed as a potential therapeutic option to alleviate the harmful metabolic effects of HHcy conditions. The findings from this study have been summarized in Fig. 23 highlighting the sequential events during HHcy and its effects on skeletal muscle atrophy.

FUTURE DIRECTIONS

HHcy-mediated skeletal muscle dysfunction involves a great number of cytokines, DNA methylation, metabolic alterations, hormonal regulation, etc. (7). The primary focus of this study was to determine how HHcy promotes skeletal muscle myopathy through induction of oxidative and ER-stress responses, apoptosis, atrophy, and impairment of angiogenesis, and to study whether or not H₂S could mitigate the effects of HHcy during skeletal muscle myopathy. Although this study was able to demonstrate the above effects, there are many other factors and signaling pathways that need to be determined to devise any effective and potential treatment to improve these detrimental effects of HHcy in skeletal muscle dysfunction.

As I showed that NaHS improved skeletal muscle functions via mitigation of cellular stress responses using CBS^{+/-} mouse model. However, people develop HHcy due to various other reasons. The western diet contains high levels of methionine (such as in red meat), and studies showed that an excessive intake of the high methionine diet could elevate Hcy levels (79,246). So, to elaborate further, I wish to study and extend my hypothesis to in a diet-induced HHcy model.

As ER is considered as a storehouse of Ca²⁺ and alterations of Ca²⁺ release from ER contributes to dysregulation of muscle's contractility. In this study, I found HHcy mediated ER-stress in muscle, however, the effects of HHcy on sarcoplasmic reticulum's Ca²⁺ handling and whether that has any role in skeletal muscle fatigability remains unresolved. In the future, I want to study the effects of HHcy on E-C coupling, Ca²⁺

release, ATP/ADP ratios, mitochondrial biogenesis in the skeletal muscle.

It has been known that aging is associated with a decline in skeletal muscle mass and strength and a slowing of muscle contraction impact the quality of life for the older people. Previous studies demonstrated that older people have significantly higher levels of Hcy compared to younger ones (387,388). It is also reported that HHcy can significantly lower physical functions in older people compared to age-matched healthy subjects (138), which suggests that aging is one of the potential risk factors to be considered in this process (139). In the future, I also want to study the role of Hcy in decline in physical function during the aging process.

Loss of skeletal muscle mass (i.e., muscle wasting) is a major component of cachexia; in particular, malnutrition is considered a critical factor (389,390). Whereas plasma total Hcy levels are dependent on nutritional status (391), deficiency of folic acid and vitamins B6, B12 and B9 are also the causal factors for the induction of HHcy (391). Since the effect of Hcy for causation of cachexia is not studied. So, in the future, I want to examine my hypothesis in light of muscle cachexia.

LIST OF ABBREVIATIONS AND SYMBOLS

HHcy:	Hyperhomocysteinemia
CBS:	Cystathionine- β -synthase
CSE:	Cystathionine γ -lyase
WT:	Wild-type
Met:	Methionine
NaHS:	Sodium hydrogen sulfide
UPR:	Unfolded protein response
IRE1 α :	Inositol-requiring enzyme-1 α
XBP-1:	X-box binding protein-1
PERK:	PRKR-like ER kinase
ATF6:	Activating transcription factor-6
TRAF2:	TNF receptor-associated factor-2
JNK:	C-Jun N-terminal kinase
ASK1:	Apoptosis signal-regulating kinase-1
FOXO:	Forkhead box protein O
MuRF1:	Muscle RING-finger protein-1
MAFBx:	Muscle atrophy F-box
MDA:	Malondialdehyde
ROS:	Reactive oxygen species
ER:	Endoplasmic reticulum
DCFDA:	2', 7'-dichlorofluorescein diacetate
ELISA:	Enzyme-linked immunosorbent assay
MHC-I:	Myosin heavy chain isoform (MHC)-I

H ₂ S:	Hydrogen sulfide
FAL:	Femoral artery ligation
HIF1 α :	Hypoxia-Inducible Factor 1 α
PPAR- γ :	Peroxisome proliferator-activated receptor- γ
VEGF:	Vascular endothelial growth factor
eNOS:	Endothelial nitric oxide synthase
EC:	Endothelial cell
DNMT:	DNA methyltransferase
MS:	Methionine synthase
SAH:	S-adenosyl Hcy
THF:	Tetrahydrofolate
GPx:	Glutathione peroxidase
SOD:	Superoxide dismutase
CAT:	Catalase

Majumder A, Singh M, Behera J, Theilen NT, George AK, Tyagi N, Metreveli N, Tyagi SC. Hydrogen sulfide alleviates hyperhomocysteinemia-mediated skeletal muscle atrophy via mitigation of oxidative and endoplasmic reticulum stress injury. *Am J Physiol Cell Physiol* 315: C609–C622, 2018. First published August 15, 2018; doi:10.1152/ajpcell.00147.2018.—Although hyperhomocysteinemia (HHcy) occurs because of the deficiency in cystathionine- β -synthase (CBS) causing skeletal muscle dysfunction, it is still unclear whether this effect is mediated through oxidative stress, endoplasmic reticulum (ER) stress, or both. Nevertheless, there is no treatment option available to improve HHcy-mediated muscle injury. Hydrogen sulfide (H_2S) is an antioxidant compound, and patients with CBS mutation do not produce H_2S . In this study, we hypothesized that H_2S mitigates HHcy-induced redox imbalance/ER stress during skeletal muscle atrophy via JNK phosphorylation. We used CBS^{+/-} mice to study HHcy-mediated muscle atrophy, and treated them with sodium hydrogen sulfide (NaHS; an H_2S donor). Proteins and mRNAs were examined by Western blots and quantitative PCR. Proinflammatory cytokines were also measured. Muscle mass and strength were studied via fatigue susceptibility test. Our data revealed that HHcy was detrimental to skeletal mass, particularly gastrocnemius and quadriceps muscle weight. We noticed that oxidative stress was reversed by NaHS in homocysteine (Hcy)-treated C2C12 cells. Interestingly, ER stress markers (GRP78, ATF6, pIRE1 α , and pJNK) were elevated in vivo and in vitro, and NaHS mitigated these effects. Additionally, we observed that JNK phosphorylation was upregulated in C2C12 after Hcy treatment, but NaHS could not reduce this effect. Furthermore, inflammatory cytokines IL-6 and TNF- α were higher in plasma from CBS as compared with wild-type mice. FOXO1-mediated Atrogin-1 and MuRF-1 upregulation were attenuated by NaHS. Functional studies revealed that NaHS administration improved muscle fatigability in CBS^{+/-} mice. In conclusion, our work provides evidence that NaHS is beneficial in mitigating HHcy-mediated skeletal injury initiated by oxidative/ER stress responses.

cellular stress; cystathionine- β -synthase; inflammation; muscle atrophy; reactive oxygen species

INTRODUCTION

Homocysteine (Hcy) is a sulfur-containing non-proteinogenic amino acid that is generated during methionine metabo-

lism via the methionine cycle (57). In healthy subjects, synthesis and elimination of Hcy are balanced; however, if Hcy metabolism is disturbed, then its plasma levels are elevated, leading to hyperhomocysteinemia (HHcy) (13, 53, 64, 65, 73). Children born with HHcy due to cystathionine- β -synthase (CBS) deficiency die shortly after birth, but children heterozygous for CBS mutation (CBS^{+/-}) can survive (22, 65, 66). How HHcy triggers such pathological effects in skeletal muscle are not fully understood.

Previous studies revealed that Hcy contains an -SH group like thiols (RSH), which can undergo oxidation to form a disulfide (RSSR) even at physiological pH in the presence of metal catalysts and molecular oxygen [O_2] (18). Further, Hcy can also produce hydrogen peroxide (H_2O_2 , a pro-oxidant molecule) during metal-catalyzed oxidation step and peroxynitrite ($ONOO^-$, a powerful oxidant) in the presence of nitric oxide (NO) and superoxide anion ($O_2^{\cdot -}$) (29). Although these phenomena have been studied in multiple tissue types, whether HHcy exerts its detrimental effects on muscle through these mechanisms is not yet elucidated. Oxidative stress has been implicated in many diseases associated with protein misfolding (36, 39, 62). Likewise, studies have also reported that HHcy could induce endoplasmic reticulum (ER) stress in hepatocytes as well as in vascular endothelial and aortic smooth muscle cells, but the cellular pathways that are involved in these stress-related conditions are not adequately studied (69, 76). It is well known that after translation the protein folding occurs inside the ER, but during stress conditions misfolded proteins can accumulate inside ER lumen, inducing the unfolded protein response (UPR) (42). In mammals, there are three branches of UPR: inositol-requiring enzyme-1 (IRE1), PERK-like ER kinase (PERK), and activating transcription factor-6 (ATF6) (23, 37, 50). During severe ER stress conditions, activated IRE1 α recruits TNF receptor-associated factor-2 (TRAF2) and apoptosis signal-regulating kinase-1 (ASK1), which further activate c-Jun N-terminal kinase (JNK) (6, 26, 52). Activation of JNK phosphorylates c-Jun at Ser63 and 73 residues in NH₂-terminal (7, 10). JNK along with c-Jun makes up the activator protein-1 (AP-1) transcription factor, which regulates the expression of several proinflammatory genes (16, 21). JNK also regulates maturation and activity of T cells in addition to the synthesis of proinflammatory cytokines, such as interleukin-2 (IL-2), IL-6, and TNF- α (14, 40, 72). Whether

Abstract

Neoangiogenesis is a fundamental process which helps to meet energy requirements, tissue growth, and wound healing. Although previous studies showed that Peroxisome proliferator-activated receptor (PPAR- γ) regulates neoangiogenesis via upregulation of vascular endothelial growth factor (VEGF), and both VEGF and PPAR- γ expressions were inhibited during hyperhomocysteinemic (HHcy), whether these two processes could trigger pathological effects in skeletal muscle via compromising neoangiogenesis has not been studied yet. Unfortunately, there are no treatment options available to date for ameliorating HHcy-mediated neoangiogenic defects. Hydrogen sulfide (H₂S) is a novel gasotransmitter that can induce PPAR- γ levels. However, patients with cystathionine- β -synthase (CBS) mutation(s) cannot produce a sufficient amount of H₂S. We hypothesized that exogenous supplementation of H₂S might improve HHcy-mediated poor neoangiogenesis via the PPAR- γ /VEGF axis. To examine this, we created a hind limb femoral artery ligation (FAL) in CBS^{+/-} mouse model and treated them with GYY4137 (a long-acting H₂S donor compound) for 21 days. To evaluate neoangiogenesis, we used barium sulfate angiography and laser Doppler blood flow measurements in the ischemic hind limbs of experimental mice post-FAL to assess blood flow. Proteins and mRNAs levels were studied by Western blots and qPCR analyses. HIF1- α , VEGF, PPAR- γ and p-eNOS expressions were attenuated in skeletal muscle of CBS^{+/-} mice after 21 days of FAL in comparison to wild-type (WT) mice, that were improved via GYY4137 treatment. We also found that the collateral vessel density and blood flow were significantly reduced in post-FAL CBS^{+/-} mice compared to WT mice and these effects were ameliorated by GYY4137. Moreover, we found that plasma nitrite levels were decreased in post-FAL CBS^{+/-} mice compared to WT mice, which were mitigated by GYY4137 supplementation. These results suggest that HHcy can inhibit neoangiogenesis via antagonizing the angiogenic signal pathways encompassing PPAR- γ /VEGF axis and that GYY4137 could serve as a potential therapeutic to alleviate the harmful metabolic effects of HHcy conditions.

Introduction

Homocysteine (Hcy) has been studied extensively for over 30 years for its unique involvement in an increasing number of human diseases (Hankey and Eikelboom 1999;

Narayanan et al. 2014; Stipanuk and Ueki 2011). The Hcy level is controlled by two major processes: around 50% of Hcy enters the transsulfuration pathway to produce cysteine, and the other half is remethylated back to methionine (Met) via the folate 1-carbon cycle (Cascella et al.

Remote ischemic conditioning as a cytoprotective strategy in vasculopathies during hyperhomocysteinemia: An emerging research perspective

Abstract

Higher levels of nonprotein amino acid homocysteine (Hcy), that is, hyperhomocysteinemia (HHcy) (~5% of general population) has been associated with severe vasculopathies in different organs; however, precise molecular mechanism(s) as to how HHcy plays havoc with body's vascular networks are largely unknown. Interventional modalities have not proven beneficial to counter multifactorial HHcy's effects on the vascular system. An ancient Indian form of exercise called 'yoga' causes transient ischemia as a result of various body postures however the cellular mechanisms are not clear. We discuss a novel perspective wherein we argue that application of remote ischemic conditioning (RIC) could, in fact, deliver anticipated results to patients who are suffering from chronic vascular dysfunction due to HHcy. RIC is the mechanistic phenomenon whereby brief episodes of ischemia-reperfusion events are applied to distant tissues/organs; that could potentially offer a powerful tool in mitigating chronic lethal ischemia in target organs during HHcy condition via simultaneous reduction of inflammation, oxidative and endoplasmic reticulum stress, extracellular matrix remodeling, fibrosis, and angiogenesis. We opine that during ischemic conditioning our organs cross talk by releasing cellular messengers in the form of exosomes containing messenger RNAs, circular RNAs, anti-pyrototic factors, protective cytokines like musclin, transcription factors, small molecules, anti-inflammatory, antiapoptotic factors, antioxidants, and vasoactive gases. All these could help mobilize the bone marrow-derived stem cells (having tissue healing properties) to target organs. In that context, we argue that RIC could certainly play a savior's role in an unfortunate ischemic or adverse event in people who have higher levels of the circulating Hcy in their systems.

ABSTRACT

In the United States, breast cancer is the second leading cause of death among women, and even though different therapies can treat primary breast tumors, most breast cancer-related deaths (>95%) occur due to metastasis. A majority (~70%) of breast tumors are found to express estrogen receptor, and a significant portion (~90%) of ER-positive (ER⁺) breast tumors are also androgen receptor-positive (AR⁺). Although ER is known to promote tumorigenesis, the role and underlying mechanism(s) of AR in these closely knit processes remain controversial. Endocrine therapies are the most commonly used treatment for patients with ER⁺ breast tumors; but, ~30%-50% of initially responsive patients develop resistance to these therapies. Whereas 70%-90% of all breast tumors are AR⁺ and AR overexpression is correlated with endocrine resistance, but the precise molecular mechanism(s) for this association is yet to be studied. Multiple mechanisms have been proposed to show AR and ER interactions, which indicate that AR may preferentially regulate expression of a subset of ER-responsive genes and that may be responsible for breast cancer and its progression in affected patients. On the other hand, most of the ER⁺ breast tumors found in post-menopausal women (~80%); and they have very low 17 β -estradiol and high androgen levels, but how these hormonal changes make someone more prone to cancer phenotype has long been a disputed issue. In this study, we have discussed multiple molecular mechanisms that we believe are central to the understanding of the overall contributions of AR in breast cancer and its metastasis in post-menopausal women.

INTRODUCTION

In the United States, breast cancer is the second leading cause of death among women (40,610 deaths and 252,710 new cancer cases are estimated in 2017) [1]. There are different therapies (surgery, radiotherapy, chemotherapy, endocrine therapies, or combination of these therapies) available which can treat primary tumor; however, most breast cancer-related deaths occur due to distant organ metastasis (mainly lung, brain and liver). Whereas, most epidemiological studies showed

inconsistent finding in a correlation between serum androgen levels and breast cancer risk; but whether this association is consistent in post-menopausal women with breast cancers (who have high androgens levels and low 17 β -estradiol) is not understood [2–11]. Previous studies have implicated a possible role for AR in breast cancers [12–14], and AR is found to be predominantly expressed in *in-situ*, invasive and metastatic breast cancers (~90% of primary tumors and 75% of metastases) [15–18]; however, the precise molecular mechanism(s) for AR's contribution to breast cancer is largely unknown. Hence, a

Hypermethylation: Causes and Consequences in Skeletal Muscle Myopathy

ABSTRACT

A detrimental consequence of hypermethylation is hyperhomocysteinemia (HHcy), that causes oxidative stress, inflammation, and matrix degradation, which leads to multi-pathology in different organs. Although, it is well known that hypermethylation leads to overall gene silencing and hypomethylation leads to overall gene activation, the role of such process in skeletal muscle dysfunction during HHcy condition is unclear. In this study, we emphasized the multiple mechanisms including epigenetic alteration by which HHcy causes skeletal muscle myopathy. This review also highlights possible role of methylation, histone modification, and RNA interference in skeletal muscle dysfunction during HHcy condition and potential therapeutic molecules, putative challenges, and methodologies to deal with HHcy mediated skeletal muscle dysfunction. We also highlighted that B vitamins (mainly B12 and B6), with folic acid supplementation, could be useful as an adjuvant therapy to reverse these consequences associated with this HHcy conditions in skeletal muscle. However, we would recommend to further study involving long-term trials could help to assess efficacy of the use of these therapeutic agents. *J. Cell. KEY WORDS: HYPERMETHYLATION; HOMOCYSTEINE; OXIDATIVE STRESS; MUSCLE DYSFUNCTION; ECM REMODELING

Hyperhomocysteinemia (HHcy/HHCY) is a complex metabolic multifactorial disorder with defects in Hcy (thiol-containing amino acid) metabolism with high prevalence in the general population (~5%) [Brustolin et al., 2010]. HHcy is typically caused either by genetic defects in the enzymes involved in Hcy metabolism (e.g., 677C>T and 1298A>C polymorphism in methylene tetrahydrofolate reductase MTHFR gene) or by nutritional deficiencies in vitamin B12, B6, and folate [Brustolin et al., 2010; Picker and Levy, 2014]. There are also several factors such as age, sex, physical activity, alcohol intake, certain medications, and different disease conditions that can modulate the Hcy level in blood [Ames et al., 2002; Van Guldener, 2006; Signorello et al., 2007; Neuman et al., 2013; Choi et al., 2015]. Depending upon severity of this HHcy conditions it can be classified as follows: (1) moderate HHcy: 15 and 30 $\mu\text{mol/L}$; (2) intermediate HHcy: 30–100 $\mu\text{mol/L}$; and (3) severe HHcy: >100 $\mu\text{mol/L}$ [Tiahou et al., 2009]. Hcy is produced during the methionine (MET) cycle, where dietary MET is first converts to S-adenosylmethionine (SAM), then SAM converts to S-adenosylhomocysteine(SAH), which then, finally converts to Hcy [Veeranki and Tyagi, 2013]. The plasma level of Hcy is controlled by two processes: either Hcy is degraded to cysteine via

transsulfuration reaction using cystathionine beta synthase (CBS), cystathionine γ -lyase (CSE) enzyme, and B6 as a cofactor or Hcy can be re-methylated to MET by MET-synthase using vitamin B12 as a cofactor and MTHF as the methyl donor through folate cycle [Veeranki and Tyagi, 2013]. In normal conditions, the synthesis and elimination of Hcy are in balance (~50% being re-methylated and ~50% eliminated) [Cascella et al., 2015], however, in diseased state the rate of cellular Hcy synthesis is faster than the elimination, which leads to excess release of Hcy into the blood circulation, and this condition is known as HHcy (Fig. 1) [Cascella et al., 2015].

HHcy is well accepted risk factor for vascular diseases [Markand et al., 2015], however, several studies also reported that HHcy conditions leads to skeletal muscle weakness and functional impairment [Veeranki and Tyagi, 2013; Picker and Levy, 2014]. Children born with severe homocystinuria due to CBS deficiency exhibit poor body weight, skeletal muscle myopathy, and die in teenage [Picker and Levy, 2014], whereas HHcy condition displays decreased bodyweight and skeletal muscle mass, which ultimately leads to muscle myopathy [Veeranki and Tyagi, 2013]. Results from our laboratory in this field, previously, showed that the expression of CBS and CSE were very less in skeletal muscles, which increases the

Connecting homocysteine and obesity through pyroptosis, gut microbiome, epigenetics, peroxisome proliferator-activated receptor γ , and zinc finger protein 407¹

Anwesha Laha, Avishek Majumdar, Mahavir Singh, and Suresh C. Tyagi

Abstract: Although homocysteine (Hcy), a part of the epigenome, contributes to cell death by pyroptosis and decreases peroxisome proliferator-activated receptor γ (PPAR γ) levels, the mechanisms are unclear. Hcy is found in high concentrations in the sera of obese individuals, which can elicit an immune response as well by hypermethylating CpG islands of specific gene promoters, a marker of epigenetics. Hcy has also been established to chelate divalent metal ions like Cu²⁺ and Zn²⁺, but this role of Hcy has not been established in relationship with obesity. It has been known for a while that PPAR γ dysregulation results in various metabolic disorders including glucose and lipid metabolism. Recently, zinc finger protein 407 (Zfp407) is reported to regulate PPAR γ target gene expression without affecting PPAR γ transcript and protein levels by synergistically working with PPAR γ . However, the mechanism(s) of this synergy, as well as other factors contributing to or inhibiting this synergism, have not been proven. This review suggests that Hcy contributes to pyroptosis, changes gut microbiome, and alters PPAR γ -dependent mechanism(s) via Zfp407-mediated upregulated adipogenesis and misbalanced fatty acid metabolism, which can predispose to obesity and, consequently, obesity-related metabolic disorders.

Key words: PGC-1 α , zinc finger protein, DNA methylation, lipopolysaccharide, fatty acid metabolism, type 2 diabetes, insulin.

Résumé : Bien que l'on sache que l'homocystéine (Hcy), une partie de l'épigénome, contribue à la mort cellulaire par la pyroptose et qu'elle entraîne une diminution des taux de récepteurs γ activés par les proliférateurs de peroxysomes (ou PPAR γ pour « peroxisome proliferator-activated receptor γ »), les modes d'action demeurent à éclaircir. On trouve de l'Hcy à concentration élevée dans le sérum de personnes obèses, ce qui peut aussi provoquer une réaction immunitaire par l'hyperméthylation des îlots CpG de promoteurs de gènes spécifiques, un marqueur de l'épigénétique. On a aussi établi que l'Hcy entre en chélation avec des ions métalliques divalents comme Cu²⁺ et Zn²⁺, mais ce rôle de l'Hcy n'a pas été établi en relation avec l'obésité. On sait depuis un certain temps que la dérégulation des PPAR γ entraîne diverses maladies d'ordre métabolique mettant en jeu le métabolisme du glucose et des lipides. On a rapporté récemment que la protéine à doigt de zinc 407 (Zfp407) participe à la régulation de l'expression de gènes cibles des PPAR γ sans modifier les taux de transcrits et de protéines des PPAR γ en agissant en synergie avec les PPAR γ . Cependant, le ou les modes d'action de cette synergie, ainsi que d'autres facteurs contribuant à cette synergie ou à son inhibition ne sont pas appuyés par des données probantes. Cet article de synthèse laisse entrevoir que l'Hcy participe à la pyroptose et entraîne des modifications du microbiome entérique et d'éventuellement plusieurs modes d'action dépendants des PPAR γ par l'intermédiaire de la régulation à la hausse de l'adipogenèse et d'un déséquilibre de la régulation du métabolisme des acides gras, tous deux médiés par la Zfp407, ce qui peut prédisposer à l'obésité et consécutivement aux maladies d'ordre métabolique liées à l'obésité. [Traduit par la Rédaction]

Homocysteine (Hcy) and obesity

Obesity is one of the leading causes of health complications like type 2 diabetes, stroke, hypertension, cardiovascular diseases, and even some cancers. As of 2014, the World Health Organization stated that 1 in 5 individuals in the United States died due to obesity-related health disorders. Per Center for Disease Control, 20% of the population in every state in the United States is obese (World Health Organization, Center for Disease Control). Obesity is responsible for causing the insulin resistance leading to dys-regulated lipid metabolism by reducing adipogenesis and increasing free fatty acids in the blood (Harmancey and Smith 2007; Kim et al. 2000; Odegaard and Chawla 2013).

Hcy is a non-protein amino acid that is generated during methionine metabolism. The fate of Hcy is either remethylation to methionine or conversion to cysteine through the transsulfuration pathway. Folic acid works as the cofactor essential for remethylation of Hcy to methionine (Barshop 2012). The 2 essential enzymes required for Hcy to cysteine transsulfuration are cystathionine β -synthase and cystathionine γ -lyase (Fig. 1). In the rate-limiting step, cystathionine β -synthase catalyzes the synthesis of the intermediate, cystathionine from Hcy, and cystathionine γ -lyase converts cystathionine to cysteine. Hyperhomocysteinemia (HHcy) is a medical condition that is characterized by the Hcy level that is more than 15 μ mol/L. Hcy in the blood due to the

Diabetic patients suffer from a host of physiological abnormalities beyond just those of glucose metabolism. These abnormalities often lead to systemic inflammation via modulation of several inflammation-related genes, their respective gene products, homocysteine metabolism, and pyroptosis. The very nature of this homeostatic disruption re-sets the overall physiology of diabetics via upregulation of immune responses, enhanced retinal neovascularization, upregulation of epigenetic events, and disturbances in cells' redox regulatory system. This altered pathophysiological milieu can lead to the development of diabetic retinopathy (DR), a debilitating vision-threatening eye condition with microvascular complications. DR is the most prevalent cause of irreversible blindness in the working-age adults throughout the world as it can lead to severe structural and functional remodeling of the retina, decreasing vision and thus diminishing the quality of life. In this manuscript, we attempt to summarize recent developments and new insights to explore the very nature of this intertwined crosstalk between components of the immune system and their metabolic orchestrations to elucidate the pathophysiology of DR. Understanding the multifaceted nature of the cellular and molecular factors that are involved in DR could reveal new targets for effective diagnostics, therapeutics, prognostics, preventive tools, and finally strategies to combat the development and progression of DR in susceptible subjects.

ABSTRACT

Cystathionine- β -synthase (CBS) gene encodes L-serine hydrolyase which catalyzes β -reaction to condense serine with homocysteine (Hcy) by pyridoxal-5'-phosphate helps to form cystathionine which in turn is converted to cysteine. CBS resides at the intersection of transmethylation, transsulfuration, and remethylation pathways, thus lack of CBS fundamentally blocks Hcy degradation; an essential step in glutathione synthesis. Redox homeostasis, free-radical detoxification and one-carbon metabolism (Methionine-Hcy-Folate cycle) require CBS and its deficiency leads to hyperhomocysteinemia (HHcy) causing retinovascular thromboembolism and eye-lens dislocation along with vascular cognitive impairment and dementia. HHcy results in retinovascular, coronary, cerebral and peripheral vessels' dysfunction and how it causes metabolic dysregulation predisposing patients to serious eye conditions remains unknown. HHcy orchestrates inflammation and redox imbalance via epigenetic remodeling leading to neurovascular pathologies. Although circular RNAs (circRNAs) are dominant players regulating their parental genes' expression dynamics, their importance in ocular biology has not been appreciated. Progress in gene-centered analytics via improved microarray and bioinformatics are enabling dissection of genomic pathways however there is an acute under-representation of circular RNAs in ocular disorders. This study undertook circRNAs' analysis in the eyes of CBS deficient mice identifying a pool of 12532 circRNAs, 74 exhibited differential expression profile, ~27% were down-regulated while most were up-regulated (~73%). Findings also revealed several microRNAs that are specific to each circRNA suggesting their roles in HHcy induced ocular disorders. Further analysis of circRNAs helped identify novel parental genes that seem to influence certain eye disease phenotypes.

1. Introduction

Our current understanding of circular RNAs (circRNAs) mediated cellular gene expression phenomena that are responsible for a multitude of molecular pathways is still naïve partly because their putative roles in the context of health and disease are under intense investigations. In comparison to other tissues, circRNAs appears to be highly enriched in the central nervous system (CNS) (Rybak-Wolf et al., 2015; You et al., 2015). Regarding their roles in eyes, the limited availability of literature about their abundance makes it difficult to study their structural and functional aspects pertaining to important ocular

disorders (Han et al., 2017; Luo et al., 2017; Zhang et al., 2017). CircRNAs are considered as new class of non-coding entities but endowed with significant regulatory abilities through their protein or miRNA "sponging" abilities thereby effectively controlling mRNA transcription and translation machineries (Hansen et al., 2013; Memczak et al., 2013).

In the past, many microRNAs (miRNAs) have been identified and subsequently characterized inside cells and tissues of the eye, however; the expression levels of the circRNAs that are responsible for regulating them have not been fully studied. Although public databases provide some information about circRNAs abundance in other tissues of mouse

Abstract

• Age-related macular degeneration (AMD) is a leading cause of blindness and is becoming a global crisis since affected people will increase to 288 million by 2040. Genetics, age, diabetes, gender, obesity, hypertension, race, hyperopia, iris-color, smoking, sun-light and pyroptosis have varying roles in AMD, but oxidative stress-induced inflammation remains a significant driver of pathobiology. Eye is a unique organ as it contains a remarkable oxygen-gradient that generates reactive oxygen species (ROS) which upregulates inflammatory pathways. ROS becomes a source of functional and morphological impairments in retinal pigment epithelium (RPE), endothelial cells and retinal ganglion cells. Reports demonstrated that hydrogen sulfide (H₂S) acts as a signaling molecule and that it may treat ailments. Therefore, we propose a novel hypothesis that H₂S may restore homeostasis in the eyes thereby reducing damage caused by oxidative injury and inflammation. Since H₂S has been shown to be a powerful antioxidant because of its free-radicals' inhibition properties in addition to its beneficial effects in age-related

conditions, therefore, patients may benefit from H₂S salubrious effects not only by minimizing their oxidant and inflammatory injuries to retina but also by lowering retinal glutamate excitotoxicity.

INTRODUCTION

Similar to many aging diseases such as neurodegeneration, diabetes, cancer and atherosclerosis, role of ocular inflammation mediated by the disruption of redox homeostasis has been studied extensively in age-related macular degeneration (AMD)^[1]. Since retina is one of the highest oxygen consuming tissues in our body, it generates significant reactive oxygen species (ROS) moieties and related radical contents (Figure 1), which makes it vulnerable to oxidative injury over time^[2-3]. A large amount of oxygen resides in the choroid and as oxygen tension falls across retinal pigment epithelium (RPE) and outer retina, it creates a vast oxygen gradient towards inner segments of the eyes' photoreceptor components. Also, photoreceptors in the retina contain relatively high levels of polyunsaturated fatty acids (PUFA) in comparison to other tissues. ROS-initiated lipid peroxidation reactions also generate reactive carbonyl compounds (RCC) from these biological lipids which further adds fuel to chronic neurodegenerative conditions such retinal degeneration^[4]. Due to continuous accumulation of lipofuscin, which causes photo-oxidative damage (lipofuscin is a product of oxidation of lipids and lipoproteins containing photo-oxidative fluorophores such as green light-emitting retinol and retinyl esters), together with other photosensitizers. Abundant light exposure and a high metabolic demand make retina a prime location for the oxidative damage (Figure 1). The non-degradable

Expression Analysis of the Circular RNA Molecules in the Human Retinal Cells Treated with Homocysteine

ABSTRACT

Purpose: To characterize the global profile of circular RNAs (circRNAs) and their differential expression levels in homocysteine (Hcy)-treated ARPE-19 cells, a line of human retinal pigment epithelial (RPE) cells. **Materials and Methods:** We treated ARPE-19 cells with and without Hcy to investigate the influence of Hcy on circRNA expression levels using dedicated human circRNA microarrays.

Results: A total of 12,233 circRNAs were identified out of them 54 were differentially expressed (17 were down-regulated, and 37 were up-regulated) with a fold change >2.0 ($p < 0.05$) in Hcy-treated versus untreated cells.

Conclusions: To our knowledge, this is the first report profiling circRNAs in human RPE cells post-Hcy treatment mimicking hyperhomocysteinemic (HHcy) conditions that negatively affect retinal biology and vision. These findings are of potential clinical significance as it will help understand Hcy metabolism and HHcy-mediated diseases and identify potential diagnostic and therapeutic targets for eye diseases that are caused by elevated Hcy concentrations.

Introduction

Retinovascular disease, comprised primarily of diabetic retinopathy (DR) and retinal vein occlusion (RVO), is a major cause of vision loss in the working age population. Its cardinal features are vascular leakage, inflammation, thrombosis, and angiogenesis.^{1–5} Despite advances in anti-angiogenic treatment in ophthalmology, the retinovascular disease still causes significant morbidity. Recently, circRNAs have been shown to regulate RNA and protein expression in the retina.⁶ Circular RNAs (circRNAs) are a recently re-discovered class of endogenous RNAs that are generated from exons, introns, or both via a diverse number of cellular mechanisms. Rapid progress in high-throughput sequencing and bioinformatics has revealed that many circRNAs can modulate expression of microRNAs (miRNAs or miRs).^{7–10} More importantly, circRNAs fine-tune post-transcriptional expression via their interactions with miRNAs or with single or multiple RNA-binding proteins.⁸

In the eye, circRNAs can either promote ocular homeostasis and normal function or contribute to disease. For example, circRNA-ZNF609 can rescue vascular endothelial dysfunction in an oxygen-induced retinopathy model whereas CircHIIPK3 plays a negative role in DR.^{11,12} Identification of circRNAs that are expressed in retinal pigment epithelial

(RPE) cells could shed light on their role in the eye, especially under hyperhomocysteinemic (HHcy) conditions. This could also assist in finding clinical biomarkers for treatment of retinal disorders. To the best of our knowledge, no study has examined circRNAs under HHcy conditions in the human eyes. This study sought to characterize the global profile of circRNAs in RPE cells under HHcy conditions. The RPE is an essential monolayer of cells immediately deep to the neurosensory retina which provides it with nutrition, allows the diffusion of oxygen to the outer retina, and phagocytoses outer photoreceptor segments to keep these cells functional. The proper function of the RPE is also critical to the maintenance of the blood-retina barrier (BRB). An intact BRB prevents the accumulation of serous fluid under or potentially within the outer retina, which are common structural complications of retinovascular disease and the most common cause of vision loss in both DR and RVO.¹³ Thus, a better understanding of RPE pathobiology is instrumental to better understanding of retinovascular disease in general. Diabetics are known to have increased levels of serum homocysteine (Hcy), which correlates with the level of DR severity.¹⁴ Moreover, HHcy conditions disrupt the BRB in retinal endothelial cells and disrupt RPE cell structure and function.^{4,15} Thus, HHcy-treated ARPE-19 cells are a model for studying the molecular and cellular effects of the

ABSTRACT

Elevated homocysteine (Hcy), i.e., hyperhomocysteinemia (HHcy) causes skeletal muscle myopathy. Among many cellular and metabolic alterations caused by HHcy, oxidative and endoplasmic reticulum (ER)-stress are considered the major ones; however, the precise molecular mechanism(s) in this process is unclear. Nevertheless, there is no treatment option available to treat HHcy-mediated muscle injury. Hydrogen sulfide (H₂S) is increasingly recognized as a potent anti-oxidant, anti-apoptotic/necrotic/pyroptotic, and anti-inflammatory compound and also has been shown to improve angiogenesis during ischemic injury. Patients with CBS mutation produce less H₂S, making them vulnerable to Hcy-mediated cellular damage. Many studies reported bidirectional regulation of ER-stress in apoptosis through JNK activation, and concomitant attenuation of cell proliferation and protein synthesis via PI3K/AKT axis. Whether H₂S mitigates these detrimental effects of HHcy on muscle remains unexplored. In this review, we discuss molecular mechanisms of HHcy-mediated oxidative/ER-stress responses, apoptosis, angiogenesis, and atrophic changes in skeletal muscle and how H₂S can restore skeletal muscle homeostasis during HHcy condition. This review also highlights the molecular mechanisms on how H₂S could be developed as a clinically relevant therapeutic option for chronic conditions that are aggravated by HHcy.

ABSTRACT

CircRNAs are a new class of covalently closed transcripts that are produced via back-splicing. These molecules have been identified in organisms ranging from worm to plants. Research on circRNAs is an active area because of their diverse roles in health and in diseases. Their circularity makes them resistant to degradation thus they hold great promise as unique biomarkers. We believe that further work on their applications could help in developing them as "first-in-class" diagnostics, therapeutics, and prognostic targets for eye conditions. Many circRNAs play roles in transcriptional regulation by acting as miRNAs sponges. Since retina is an extension of brain and is part of CNS, we highlight the current state of circRNA biogenesis, properties and function and we review the crucial roles they play in the eye and brain. We also discuss their roles as miRNA sponges, regulation of genes or linear mRNAs, translation into micro-peptides/proteins, and responses to cellular stress. We posit that future advances will provide newer insights in the fields of RNA metabolism in general and diseases of the aging eye and brain. Furthermore, in keeping pace with the rapidly evolving discipline of RNA'omics'-centered metabolism and to achieve uniformity among researchers, we recently introduced the term "cromics"

PREVIOUS RESEARCH EXPERIANCES:

Last Employed: Research Fellow at Institute of Human Genetics, Genetic Centre, India (2nd April 2012 to 31st March 2014)

Project Title: “Effect of genetic variations in *PPAR γ -2* and *ADR β -3* gene in type 2 diabetic subjects of Gujarat, in relation to drug response”; Funding agency: Gujarat Institute of Chemical Technology (GICT). Institution: Foundation for Research in Human Genetics and Endocrinology, Institute of Human Genetics. Guide: Jayesh J Sheth, Ph.D., Director, Institute of Human Genetics (MS University affiliated)

1) From 2nd November 2011 to 28th March, 2012:

Project Title: “A Polymorphism in the Gene for *IGF-1* and its Functional Properties and Risk for Type 2 Diabetes and Myocardial Infarction”

Institution: Molecular biology Dept, Galaxy Concepts Private Limited (ISO 9001-2008 certified), Kolkata, India. **Guide:** Dr. Prianka Pusp Research associate and faculty in Galaxy Concepts Private Limited.

Brief Description: There are many evidences that low levels of *IGF-1* play a role in the pathogenesis of type 2 diabetes and cardiovascular diseases. I studied the role of a genetic polymorphism in the promoter region of the *IGF-1* gene and measured anthropometric indices and other biochemical parameters along with genotyping. **Conclusion:** My study suggests that a genetically determined exposure to relatively low *IFG-1* levels is associated with an increased risk for type 2 diabetes and myocardial infarction.

2) From 1st October 2009 to 30th June, 2010:

Project Title: “Study of IVS 1-5 G→C mutation by ARMS-PCR method in E β -thalassaemia patients to determine genotype-phenotype correlation”. **Institution:** Institute of Genetic Engineering (Affiliated to WBUT), West Bengal, India. **Guide:** Dr. Sudipa Chakravarty, Vice Principal of Institute of Genetic Engineering.

Brief Description: I studied E β -thalassaemia patients with age ranging from 11 months to 50years. Studied Hemoglobin parameters (HbF, HbA0, HbA2) by HPLC method and CBC parameters (MCV, MCH, MCHC, HCT etc.) by Automated Cell Counter and genetic analysis was performed by ARMS-PCR for IVS 1→5 GC. **Conclusion:** a) Patients having IVS 1-5 G→C mutation are clinically less severe/ better i.e. most of these patients require either occasional or no blood transfusion. b) The Severity of the haemoglobinopathy disease process is related to genetically predetermined rate of either deficient globin chain production or complete cessation of its synthesis.

3) From 2nd October 2008 to 30th April, 2009:

Project Title: “Phenotypic analysis of SNP variants of the alpha chain of Globin protein related to haemoglobinopathy”. **Institution:** Institute of Genetic Engineering (Affiliated to WBUT), West Bengal, India. **Guide:** Dr. Amit Chakravarty, director of Institute of Genetic Engineering.

Brief Description: The PDB file of deoxy-hemoglobin was collected from RCSB-PDB database. The studies of SNPs were done by inducing previously collected mutations in deoxy hemoglobin structure by using Swiss-PDB Viewer software. Then the energy of the mutated structures was minimized using GROMACS and RMSD values were calculated using VMD. Finally, a graph was plotted against RMSD values vs. type mutations. **Conclusion:** Non-polar to polar or polar to non-polar mutations are more severe than non-polar to non-polar or polar to polar mutations.

Extra Qualifications (Certificates):

- 3 months training in Assisted Reproductive Technology in human (IVF, ICSI, IUI).
- Training in Biotechnology techniques and its application.
- Workshop on Metabolic and Molecular Diagnosis- clinical & laboratory approach.
- Certification Course in computer languages (C, C++)
- Technical Expertise - O.S. Platforms: WIN; LINUX; Mac; Scripting languages: HTML; M.S. office and other Software's.

Seminars / Conference attained (Award & Certificates):

- Annual meeting of Experimental Biology-2018, San Diego, CA, USA.
- Annual meeting of Experimental Biology-2017, Chicago, IL, USA.
- The 95th Annual Meeting & Expo Endocrine Society 2013, **San Francisco, CA, USA.**
- National Symposium on 10th Annual Conference of “Indian Society for Prenatal Diagnosis & Therapy” in Mumbai, India.
- Diabetes & its Complications: Search for Prevention & Cure, National Seminar, Ahmedabad, India.
- Award & Certificate for Best Project presentation on Post Genome impact from “1st Annual DNA Day contest” in Institute of Genetic Engineering (WBUT), West Bengal, India.
- 4th World Congress on “Mild Approaches in Assisted Reproduction” arranged by International Society for Mild Approaches in Assisted Reproduction (ISMAAR), Kolkata, India.
