DEDICATION

This dissertation is dedicated to my parents

Mr. Huiling Guo

and

Mrs. Huazi Zhang

For their love, support, and encouragement

ACKNOWLEDGEMENTS

Above all, I would like to express my deepest gratitude to my advisor, Professor Zhihui Sun, the chair of the Civil and Environmental Engineering Department at the University of Louisville, who gave me an opportunity to work on this project. Throughout my Ph.D. study, with great enthusiasm, excellent insights, and profound academic knowledge, Dr.Sun provided tremendous help to me in many aspects such as academic writing and presentation, and research implementation. Under her supervision, the project went smoothly, and I made much progress in research beyond my expectation. It is hard to find any word to express my appreciation to my advisor.

Then I would like to thank my co-advisor, Dr.Jagannadh Satyavolu, a theme leader in the Conn Center for Renewable Energy Research at the University of Louisville. Not only he provided financial aids to me for three years but also provided me an opportunity to access many advanced material characterization instruments and gave me much guidance on research, especially in the aspect of lignocellulosic biomass modification. There is no question that any academic achievement I have made during my Ph.D. study should be partly attributed to him.

I would like to thank my committee members, Dr. Noppadon Sathitsuksanoh, Dr. Young Hoon Kim, and Dr. McGinley William Mark. During my Ph.D. study, they put forwarded many conducive suggestions to my research and also assisted me a lot in implementing experiments.

I would like to acknowledge Dr. Chengqing Qi, the technical center director in the Ash Grove Cement Company, who helped complete some tests.

I would like to thank Dr. J. P. Mohsen, the former chair of the Civil and Environmental Engineering Department and the current associate dean of J.B. Speed School of Engineering for his kindness and help.

I appreciate the staffs in the department, Mr. Bernie Miles (our great technician) who helped me solve many problems I encountered with my experiments during the past several years and Ms. Gail Graves who kept everything going orderly and created a great environment for my working.

I also would like to thank my teammates and friends, Dr. Hong Shang, Dr. Bashir Hasanzadeh, Dr. Osama Bu Aamiri, Dr. Chamila Rajeeva Thilakaratne, Dr. Jogi Ganesh Dattatreya Tadimeti, Ms. Uyen Thi Duong, Mr. Song Wang, Mr. Li Liu, Mr. Jice Zeng, Mr. Muting Ma, Dr. Mahyar Ramezani, Dr. Xiaoming Fan, and Mr. Danming Wei, for their friendship and help at the University of Louisville.

More importantly, I would heartily like to thank my family who have been supporting me all the time.

This work has been supported by the Civil and Environmental Engineering Department and Conn Center for Renewable Energy Research at the University of Louisville. They are much appreciated.

ABSTRACT

HYDRATION, SHRINKAGE, CRACKING, AND MECHANICAL PROPERTIES OF
CEMENTITIOUS MATERIALS WITH LIGNOCELLULOSIC BIOMASS WASTES

Aoife Guo

October 30, 2020

The disposal of lignocellulosic biomass wastes imposes a huge economic and environmental burden on this society. Recycling lignocellulosic biomass wastes and applying them to cementitious materials provides a sustainable and value-added way for both agriculture and concrete industries. To comprehensively identify the effect of lignocellulosic biomass wastes at different scales on cementitious materials, the hydration, shrinkage, cracking, and mechanical properties of cementitious materials with lignocellulosic biomass wastes were studied. Given the three different forms (powders, chips, and fibers) of lignocellulosic biomass wastes in this study, the research was implemented in three stages.

In the first stage, hemp powders were collected through grinding the residual of hemp products and then chemically treated using saturated lime water to partially remove hemicellulose, lignin, and impurities. The effect of untreated and treated hemp powders on the hydration of cement paste was studied. It was found that partially replacing cement with untreated and treated hemp powders can delay cement hydration. Compared with untreated hemp powders, treated (washed or nonwashed) hemp powders showed a lower delay effect on cement hydration, distilled-water-washed treated hemp powders delayed

less than nonwashed treated hemp powders, and coarse hemp powders exerted a lower delay effect on cement hydration than fine hemp powders.

In the second stage, ground wood chips were lightly or highly torrefied and then used to partially replace sand in mortar. The effect of non-torrefied and torrefied ground wood chips on the mechanical properties of mortar was studied. Compared to the mortar containing non-torrefied ground wood chips, those containing highly or lightly torrefied ground wood chips were found to have higher flexural strength and compressive strength due to the enhanced bonding between the wood chips and paste matrix. Although all the tested mortars with ground wood chips have lower strength than the mortar without any wood chips, their toughness was found to be comparable or higher, indicating better energy absorption capacity.

In the third stage, kenaf fibers were chemically treated using different inorganic chemicals. The characteristics of raw and chemically treated kenaf fibers were investigated through a series of tests. It was found that chemically treated kenaf fibers have lower hemicellulose and extractives, lower moisture sorption capacity, and higher tensile strength and crystallinity index. And then, alkaline treated and alkaline-hydrogen peroxide treated kenaf fibers, together with raw kenaf fibers, were selected to be used as reinforcements in cementitious materials. The effect of these three types of kenaf fibers on the autogenous shrinkage, drying shrinkage cracking, and flexural behavior of cementitious materials was studied. It was found that compared to raw kenaf fibers, these two treated kenaf fibers can lead to reduced shrinkage and cracking and also improved flexural strength and toughness.

This research provides some guidance for the future application of lignocellulosic biomass at different scales to non-structural concrete elements (such as pavement and roof).

Hemp powders can be used to partially replace cement, with a dosage limit of 10% by weight of cement. Wood chips can be used to partially replace sand, with a recommended replacement level of 10% by weight of sand for OW and HTW, and a recommended replacement level of 5% for LTW. Kenaf fibers can be used as reinforcement, with a recommended dosage of 0.5% by weight of cement (or 0.12-0.24% by volume of the composites).

CHAPTER 1 INTRODUCTION

1.1 Lignocellulosic Biomass

Biomass has been defined as “substance wholly comprised of living or recently living (non-fossil) material” by ASTM (2015). Sometimes it is referred to as renewable organic material, and includes whole or parts of plants, trees, aquatic organisms, animals, algae, and microorganisms, etc. In general, it can be categorized as lignocellulosic biomass and non-lignocellulosic biomass (Li and Jiang 2017). Lignocellulosic biomass is mainly comprised of cellulose, hemicellulose, lignin, and extractives. The chains of cellulose form microfibrils, which are held together by hemicellulose and lignin to form fibrils, and then these fibrils are assembled in various layers to form the fiber structure (Correia et al. 2016). The properties of lignocellulosic biomass depend on the properties of cellulose, hemicellulose, and lignin to a large extent.

Cellulose is a semi-crystalline polysaccharide $(C_6H_{12}O_5)_n$ consisting of D-glucopyranose units joined by β -(1-4)-glycosidic linkages, as shown in **Fig. 1.1**, and the degree of polymerization can be around 10000 (Gurunathan et al. 2015; John and Thomas 2008; Li et al. 2007). It includes not only tightly packed slender rod-like crystalline microfibrils but also amorphous regions that have a lower packing density (Gurunathan et al. 2015; John and Thomas 2008). Because most of the cellulose is crystalline that is not

easily broken down, cellulose is harder to be decomposed than hemicellulose and lignin (Kabir et al. 2013). It was reported that cellulose is resistant to strong alkali and oxidizing agents but is easily hydrolyzed by acid to water-soluble sugars (John and Anandjiwala 2008). The decomposition of cellulose can produce a kind of monosaccharide called glucose ($C_6H_{12}O_6$), and each glucose unit includes three hydroxyl groups, with two of them forming intramolecular hydrogen bonds and one of them forming intermolecular hydrogen bonds (Kabir et al. 2012).

Fig. 1.1. Structure of cellulose (Gurunathan et al. 2015)

The structure of hemicellulose is more complex than cellulose, and the differences are reflected in three aspects (John and Thomas 2008). Firstly, hemicellulose is a group of homo- and heteropolymers consisting mainly of anhydro-b-(1-4)-D-xylopyranose, glucopyranose, mannopyranose, and galactopyranose main chains with several substituents (**Fig. 1.2**) (Gurunathan et al. 2015). Compared to cellulose containing only 1,4- β -D-glucopyranose units, hemicellulose contains different sugar units. Secondly, hemicellulose has a considerable degree of chain branching giving rise to its non-crystalline nature, while cellulose is a linear polymer. Thirdly, the degree of polymerization of native cellulose is 10–100 times higher than that of hemicellulose (around 50-300). Therefore, hemicellulose exhibits a different behavior from cellulose. Normally, hemicellulose decomposes at a lower temperature than cellulose and lignin (Kabir et al. 2013). It is soluble in alkali and easily hydrolyzed by acid (John and Anandjiwala 2008). Also, it was suggested that the

hydrophilic nature of lignocellulosic biomass is mainly attributed to the presence of hemicellulose (Correia et al. 2016).

Fig. 1.2. Main and side chains of hemicellulose (Gurunathan et al. 2015)

Lignin is considered as a complex, three-dimensional copolymer of aliphatic and aromatic constituents with a very high molecular weight (John and Anandjiwala 2008). Because no method has been established to isolate lignin in its native state from the lignocellulosic biomass, the exact chemical nature of lignin is not identified. But hydroxyl, methoxyl and carbonyl groups associated with lignin have been identified (John and Thomas 2008). Lignin is formed from three primary precursors: trans-coniferyl, trans-sinapyl, and trans-p-coumaryl, as shown in **Fig. 1.3** (Gurunathan et al. 2015; Mohanty et al. 2002). The only difference between the precursors is the number of methoxyl groups (-OCH_3) present on the aromatic ring. Lignin is amorphous and hydrophobic, and it has less water absorption capacity compared to cellulose and hemicellulose (Li et al. 2007). It is not hydrolyzed by acids but soluble in hot alkali, readily oxidized, and easily condensable with phenol (John and Thomas 2008). The thermal decomposition of lignin occurs over a wider temperature range than cellulose and hemicellulose because various oxygen

functional groups in lignin decompose at different temperatures (Correia et al. 2016; Kabir et al. 2013).

Fig. 1.3. Precursors of lignin (Gurunathan et al. 2015)

1.2 Application of Lignocellulosic Biomass Wastes to Cementitious Materials

In recent years, environmental issues such as global warming and energy savings are becoming more and more evident. The awareness of the importance of environmental sustainability has been increased. Lignocellulosic biomass is considered as a renewable and CO_2 neutral energy resource (Rajamma et al. 2009). It has been used worldwide for food, fodder, and processing (sugar, starch, and vegetable oils, etc.) and also in energy production industry (Medina et al. 2017). Many countries or organizations have established a series of development strategies to expand the application of lignocellulosic biomass. So far, lignocellulosic biomass has attracted much attention from the concrete industry based on some advantages in addition to its environment-friendly nature. Firstly, lignocellulosic biomass is relatively cheap and plentifully supplied worldwide. It can be obtained from woody crops, vegetable plants, and agricultural by-products, etc. Secondly, the disposal of lignocellulosic biomass wastes is a major societal problem, which costs much money and labor. However, the recycling of these wastes as raw materials for concrete provides a sustainable way to deal with these wastes for the agriculture industry. Thirdly and most importantly, the application of lignocellulosic biomass to concrete can bring many benefits to the concrete industry by reducing the use of raw materials for concrete. Concrete is the

most commonly used building material, with an annual production of over 14 billion tons, and the concrete industry accounts for 7% of global CO₂ emissions (Cuthbertson et al. 2019). Also, the concrete industry not only consumes large amounts of raw materials, considerably reducing limestone and clay resources, but also is highly energy-intensive (Medina et al. 2017). The concrete industry is challenged by environmental concerns and the consumption of raw materials and energy (Teixeira et al. 2016). The incorporation of lignocellulosic biomass wastes into concrete is a sustainable way to the concrete industry.

The use of lignocellulosic biomass wastes in cementitious materials can be accomplished in two ways, one is in the form of ash derived from burning lignocellulosic biomass wastes and the other is the direct use of lignocellulosic biomass wastes. Many kinds of lignocellulosic biomass ashes, such as rice husk ash and corn cob ash, have been used as pozzolanic materials to partially replace cement because they contain a large amount of silica in the amorphous form (Rajamma et al. 2009). The chemical characteristics of the lignocellulosic biomass ash can be affected by the operating conditions (combustion temperature and technology used) and also biomass source (herbaceous, wood, or bark) (Demis et al. 2014). However, it should be noted that the application of non-coal derived biomass ashes in concrete is still prohibited by many agencies such as the American Society of Testing Material (ASTM), American Concrete Institute (ACI), EN-450, and EN197-1 (A 2016; Barbosa et al. 2013). Regarding the direct use of lignocellulosic biomass wastes, they can be applied in the form of powders, chips, shavings, and fibers depending on their sizes. Normally, powders, chips, and shavings are used in large amounts to reduce the use of fine or coarse materials in concrete, and fibers are used as reinforcements in concrete. Research on such applications is enormous, and

some conclusions can be summarized as follows (Becchio et al. 2009; Bederina et al. 2007; Benmansour et al. 2014; Chen et al. 2017; Mohammed et al. 2014). Firstly, the weight of concrete can be reduced due to the lower specific gravity of lignocellulosic biomass, which indicates that the lightweight concrete can be developed if a sufficient amount of lignocellulosic biomass wastes is used. Secondly, the thermal and acoustic insulation capacities can be improved, which can result in huge energy savings. Thirdly, the toughness of concrete is found to be improved, which is indicative of a higher energy absorption capacity. Lastly, there are, however, some variations about the strength of concrete, and the improvement or reduction in the strength is closely dependent on the synergistic effect of lignocellulosic biomass wastes and cementitious materials.

So far, some concerns about directly using lignocellulosic biomass wastes in cementitious materials have been proposed. Firstly, hemicellulose, lignin, and impurities in lignocellulosic biomass can delay cement hydration by forming a protective layer around the partially hydrated cement grains or forming a chelate complex with the cations present in the hydrated cement (Jo and Chakraborty 2015). Besides, these organic components (hemicellulose, lignin, and impurities) can be degraded in the alkaline environment of cementitious materials, and the degree of polymerization can be reduced (Ballesteros et al. 2015; John and Anandjiwala 2008; John and Thomas 2008). The decomposition products are mainly saccharides (such as glucose and xylose), which can further delay cement hydration and affect the formation of calcium silicate hydrate that contributes the most to the strength of cementitious materials (Boix et al. 2020; Chakraborty et al. 2013; Vo and Navard 2016). Secondly, lignocellulosic biomass has high water absorption capacity, which indicates that it has poor dimensional stability, and the compatibility between

lignocellulosic biomass and the cementitious matrix will be not good. This may lead to a bad interfacial adhesion with the matrix and thus is not beneficial to the mechanical properties of cementitious materials. Thirdly, the impurities, such as pectin and wax, cover the surface of lignocellulosic biomass and hinder interlocking with cementitious matrix. In order to mitigate these negative effects of the lignocellulosic biomass and improve its application in cementitious materials, an alternative way is to modify lignocellulosic biomass.

1.3 Modification on Lignocellulosic Biomass Wastes in Cementitious Materials

So far, many different treatment methods have been proposed to modify lignocellulosic biomass in cementitious materials. They are mainly focused on changing the structure or removing amorphous components (hemicellulose, lignin, and impurities) of lignocellulose biomass, or preventing the lignocellulosic biomass from contacting with cementitious materials. The commonly used treatment methods in cementitious materials include ordinary heating treatment, torrefaction treatment, boiling treatment, surface coating or impregnation treatment, hornification treatment, alkaline treatment, bleaching treatment, and other treatments, which are introduced as follows.

1.3.1 Ordinary Heating Treatment

Ordinary heating treatment is conducted by heating the lignocellulosic biomass at a temperature, usually less than 200 °C, in an air-circulating environment. In such a temperature range, the main components of lignocellulosic biomass cannot be degraded, but the crystallinity of cellulose can be improved. Rong et al. heated sisal fibers at 150 °C in an air-circulating oven for 4 h, and the heat-treated sisal showed superior tensile properties due to the increased crystallinity of cellulose (Rong et al. 2001). Following the

same treatment temperature (150 °C), Wei et al. heated sisal for 4h, 8h, and 16h, respectively, and the sisal fiber's crystallinity was improved from 20.27% to 22.67%, 26.42%, and 23.86%, respectively (Wei and Meyer 2014). And due to the improved crystallinity of cellulose, the mechanical properties of sisal fiber were improved, which leads to an improvement in the strength and durability of sisal fiber reinforced concrete.

1.3.2 Torrefaction Treatment

Torrefaction (mild pyrolysis) treatment is conducted at a temperature between 200 and 300 °C under atmospheric pressure, with the oxygen absent (Chen et al. 2015). It has been reported that at 200-250 °C, hemicellulose starts to decompose and can be totally degraded when torrefied at 300 °C for 2 h, while cellulose and lignin begin to decompose at about 270-300 °C (Shang et al. 2012). Therefore, it can be concluded that after torrefaction, the hemicellulose component of lignocellulosic biomass can be mostly removed. Govin et al. applied three kinds of wood shavings (natural, torrefied at 240 °C, and torrefied at 260 °C) to cement paste and showed that the hydration of the silicate phases can be delayed by wood shavings, while the torrefied wood shavings can promote gypsum dissolution or consumption and ettringite formation (Govin et al. 2006). Similarly, Bilba et al. indicated that the torrefied bagasse at 200 °C and 250 °C could improve the setting of cementitious materials compared to raw bagasse (Bilba et al. 2003). Besides, Onésippe et al. indicated that torrefied bagasse fibers could reduce the thermal conductivity of cement composites significantly (Onésippe et al. 2010).

1.3.3 Boiling Treatment

Boiling treatment is conducted by immersing lignocellulosic biomass into boiling water. It can reduce the amount of water-soluble substances responsible for setting delay

and incompatibility problem with cement paste. It was found that boiling in water for 2h was sufficient to reduce water-soluble substances (Asasutjarit et al. 2007). Normally, the boiling treatment is accompanied by washing process, which can further reduce the water-soluble substances, especially sugars. Sellami et al. indicated that the water-soluble sugars could be decreased from 30.78% for untreated Diss to 1.95% for boiled-but-not-washed Diss and, eventually, to 0.72% for boiled-and-washed Diss (Sellami et al. 2013). Moreover, the boiling treatment and consequent washing process have been found to improve the fiber tensile strength, fiber toughness, and fiber-concrete bonding strength (Ali and Chouw 2013; Ali et al. 2013). And the higher compressive and flexural strengths of cementitious materials were also be observed (Asasutjarit et al. 2007; Sellami et al. 2013).

1.3.4 Surface Coating or Impregnation Treatment

Surface coating or impregnation on lignocellulosic biomass is normally conducted by using polymer coverings on its surface. The polymer can form a film to protect the lignocellulosic biomass from contacting with the cementitious materials, so the fiber degradation can be avoided. It has been widely reported that the coating with styrene-butadiene polymer could improve the bonding with matrix and also increased the tensile strength, flexural strength, and even stiffness of cementitious materials (Ferreira et al. 2015; Fidelis et al. 2016). Additionally, Ahmad and Fan compared four types of resins (epoxy, polyurethane, vinylester, and polyester) for coating sisal fibers and showed that all coatings resulted in significant improvement in interfacial bonding and mechanical properties of cementitious composites, with polyurethane coated fibers being the best (Ahmad and Fan 2018).

1.3.5 Hornification Treatment

Hornification treatment is conducted through alternatively drying and wetting of the lignocellulosic biomass. It does not change the chemical structure of lignocellulosic biomass, but the polysaccharide chains of cellulose are grouped closely together after drying, which can reduce the lumen and water absorption capacity of lignocellulosic biomass (Ballesteros et al. 2015; Lima et al. 2014). Ferreira et al. indicated that the hornification treatment could not only reduce water absorption capacity but also increased the tensile strength and stiffness of sisal fiber, leading to an improvement in the fiber-matrix interface (Ferreira et al. 2015). Ballesteros et al. applied the hornification treatment to unbleached pulp and bleached pulp and showed that the treatment did not deteriorate the properties of viscosity and crystallinity index while reducing the water retention capacity for both pulps (Ballesteros et al. 2015). This resulted in a loss of the swelling capacity and thus greater dimensional stability of pulps and consequently, an improvement in the fiber-matrix adhesion and the modulus of rupture and specific energy of composites.

1.3.6 Alkaline Treatment

Alkaline treatment, also called mercerization, is the most commonly used chemical treatment method to modify lignocellulosic biomass through the reaction of hydroxyl groups of lignocellulosic biomass with alkaline substances (John and Anandjiwala 2008). It has been reported to remove hemicellulose and some impurities of lignocellulosic biomass, and increase the crystallinity index of cellulose (Stevulova et al. 2014). The alkaline treated lignocellulosic biomass can not only reduce the negative effect on cement hydration but also roughen its surface and increase the interfacial adhesion with matrix, leading to improved mechanical properties of cementitious materials, especially flexural

strength and toughness (Andiç-Çakir et al. 2014; Arsyad et al. 2015; Boix et al. 2020; Yan et al. 2016). Sawsen et al. reported that cement composites with alkaline treated flax fibers have reduced setting time, higher stiffness and strength, and more pronounced ductility than those with untreated fibers (Sawsen et al. 2014). Snoeck et al. indicated that chemically treated flax and hemp fibers using 2% (m/m) NaOH can improve the multi-cracking property and reduce crack widths, which allows the autogenous healing when exposed to wet/dry cycles (Snoeck et al. 2015). In addition, de Klerk et al. indicated that at low concentrations of 2%, 6%, and 10% NaOH, the fiber strength, fiber-matrix bonding, and post-peak strength of cement-based composites are improved; however, higher concentrations of 20% and 30% NaOH cause the opposite result (de Klerk et al. 2020).

1.3.7 Bleaching Treatment

Bleaching treatment is a common practice to increase the whiteness of pulp for paper production. Given that the coloration mainly comes from lignin rather than hemicellulose and cellulose, the bleaching treatment targets at the removal of lignin, which has been adopted to modify lignocellulose biomass in cementitious materials. One commonly used bleaching agent is sodium chlorite (NaClO_2). The decomposition of sodium chlorite produces one of the strongest oxidizing gases, which is known as chlorine dioxide (ClO_2) (Abdel-Halim 2014). ClO_2 reacts with lignin constituents, and then the lignin can be removed (Kabir et al. 2012). Carvalho et al. indicated that after NaClO_2 treatment, lignocellulosic fibers can be disintegrated due to the extraction of lignin that holds the fibrils together, and the crystallinity index can be improved due to the increased exposure of cellulose (Carvalho et al. 2010). Another commonly used bleaching agent is hydrogen peroxide (H_2O_2). Ghali et al. indicated that a strong NaOH condition could not

affect the lignin amount significantly; however, the H_2O_2 bleaching could lead to a considerable decrease in the lignin content particularly when the concentration of H_2O_2 is increased (Amel El et al. 2012). Xie et al. reported that the H_2O_2 bleaching treatment could decrease amorphous components, especially lignin, and increase the crystallinity of rice straw, which mitigates the negative effect of rice straw on cement hydration (Xie et al. 2016). At present, H_2O_2 bleaching is gradually replacing NaClO_2 bleaching due to its environmental friendliness, although NaClO_2 bleaching can reduce lignin with minimal amounts of cellulose degradation at a reasonable cost (Ahmad et al. 2019).

1.3.8 Other Treatments

In addition to the above-mentioned treatments, some other treatments are also applied to lignocellulosic biomass in cementitious materials. Bulut et al. indicated that the oxidative modification on jute fibers with potassium dichromate and potassium permanganate reduced alcohol groups and increased $\text{O}=\text{C}$ groups, and thus led to a more hydrophobic surface, which is accompanied by the increased surface roughness (Bulut and Aksit 2013). Amiandamhen et al. treated kenaf fibers with hot water, CaCl_2 , and a combination of hot water and CaCl_2 , and concluded that cement boards produced from hot water and CaCl_2 treated fibers had the best mechanical and physical properties (Amiandamhen et al. 2016). On the contrary, Ali et al. showed that the treated fibers with 0.25% sodium alginate ($\text{NaC}_6\text{H}_7\text{O}_6$) and 1% calcium chloride (CaCl_2) solution caused a decrease in tensile strength and strain of fibers and fiber-concrete bonding strength (Ali et al. 2013).

1.4 Research Significance and Objectives

Lignocellulosic biomass is a renewable resource, and each year large amounts of lignocellulosic biomass wastes are produced across the world. However, the collection, treatment, and disposal of lignocellulosic biomass wastes can impose economic and environmental costs on this society. Recycling lignocellulosic biomass wastes to develop value-added products is becoming more and more important for agriculture industry. Meanwhile, given that concrete is the most commonly used building material, and the whole concrete industry consumes plenty of nonrenewable mineral materials and emits significant amounts of polluting gases, there is an urgent need to reduce the usage of these materials. Therefore, the application of renewable lignocellulosic biomass wastes to concrete provides a sustainable way for both agriculture and concrete industries. More importantly, the incorporation of lignocellulosic biomass wastes into concrete can bring many benefits, such as developing lightweight concrete, improving acoustic and thermal insulation performance of concrete, improving tensile strength, flexural strength, and toughness, and controlling shrinkage and cracking, etc.

The goal of this research is to explore the hydration, shrinkage, cracking, and mechanical properties of cementitious composites with lignocellulosic biomass wastes at different scales. There are three sources of lignocellulosic biomass wastes, namely hemp powders, kenaf fibers, and wood chips, in this study. Based on their unique sizes, these wastes are utilized in different ways. Meanwhile, different treatment methods are used on these wastes to achieve the desired benefits. Firstly, since the size of hemp powders is close to that of cement particles, hemp powders are preferred to partially replace cement to develop powder-type agents that can adjust the hydration rate of cement. Hemp powders

are modified by saturated lime ($\text{Ca}(\text{OH})_2$) solution. The hydration of cement pastes with untreated and treated hemp powders needs to be studied. Secondly, since the size of wood chips is close to that of standard silica sand, wood chips are preferred to partially replace sand to develop lightweight cementitious materials. Wood chips are torrefied at low (220 °C) and high (260 °C) temperatures, respectively. The mechanical properties (compressive strength, flexural strength, and toughness, etc) of mortar with non-torrefied and torrefied wood chips need to be examined. Thirdly, since kenaf fibers have a relatively large length/diameter ratio, kenaf fibers are preferred to serve as reinforcement in cementitious composites. Kenaf fibers are treated using different chemical agents such as NaOH and H_2O_2 . The effects of untreated and treated kenaf fibers on the shrinkage, cracking, and flexural properties of cementitious composites need to be studied.

1.5 Structure of the Dissertation

The dissertation is comprised of five parts. Part one provides a general introduction to lignocellulosic biomass, some treatment methods on lignocellulosic biomass, and their application in cementitious materials (Chapter 1).

Part two is related to the application of hemp powders to cementitious composites, which is introduced in Chapter 2. Hemp powders are chemically treated with saturated calcium hydroxide solution and then used to partially replace some cement in cement pastes. The hydration of cement pastes with untreated and treated hemp powders is studied.

Part three is related to the application of wood chips to cementitious composites, which is introduced in Chapter 3. Wood chips are torrefied with low and high temperature and then added to mortar to partially replace some sand. The impact of lightly and highly torrefied wood chips on the mechanical properties of mortar is introduced.

Part four is related to the application of kenaf fibers to cementitious composites, which is introduced in Chapter 4, Chapter 5, and Chapter 6. Chapter 4 focuses on the chemical modification on kenaf fibers, and the physiochemical and mechanical properties of modified kenaf fibers are evaluated through a series of tests. On top of Chapter 4, three types of kenaf fibers (raw kenaf fibers, alkaline treated kenaf fibers, alkaline-hydrogen peroxide treated kenaf fibers) are selected to be used in cementitious composites. The impact of these three types of kenaf fibers on autogenous shrinkage and drying shrinkage cracking of cement pastes is introduced in Chapter 5. Afterward, the flexural behavior of mortar with these three types of kenaf fibers is elaborated through experimental and finite element analysis in Chapter 6.

Part five is the conclusions and future work, which is introduced in Chapter 7. Conclusions from this work are summarized in this part. Also, some meaningful work that can be done in the future is introduced.

CHAPTER 2 HYDRATION OF PORTLAND CEMENT PASTES CONTAINING UNTREATED And TREATED HEMP POWDERS

2.1 Introduction

As the first study of the dissertation, this chapter addresses the direct application of lignocellulosic powders to cementitious materials. The existing studies on such a topic are very limited. The main challenge towards their good application is the delaying effect on cement hydration. Karim et al. studied the palm oil shell powder blended cement and concluded the partial replacement of cement with palm oil shell powders can increase the setting time of concrete (Karim et al. 2017). In order to mitigate the delaying effect of lignocellulosic powders on cement hydration, it's necessary to conduct treatment prior to their application.

Alkaline treatment has been reported to be the most commonly used method on lignocellulosic biomass wastes to mitigate the delaying effect. It was reported that alkaline treatment can remove the hemicellulose, lignin, pectin, and wax of lignocellulosic biomass (Lu and Oza 2011; Sawpan et al. 2011). Jo and Chakraborty reported that the mild alkali treatment on jute was demonstrated to reduce the set delaying effect on cement hydration compared to untreated jute (Jo and Chakraborty 2015). Quiroga et al. compared three different treatment methods including water extraction, alkaline hydrolysis, and retention of inhibitory substances on wood and concluded that alkaline hydrolysis was the most

effective method for minimizing the set delaying effect on cement hydration (Quiroga et al. 2016). Although there are very limited reports on the application of treated lignocellulosic powders in cementitious materials, alkaline treatment is expected to be a practical method due to the alkalinity of the cementitious materials.

In this study, the residuals of hemp products were ground into powders and then treated by a saturated lime (calcium hydroxide) solution to partially remove hemicellulose, lignin, and impurities. Untreated and alkaline treated hemp powders were used to partially replace cement, respectively. The isothermal calorimetry test, thermogravimetric analysis, fourier transform infrared spectroscopy analysis, scanning electron microscopy analysis were conducted on cement pastes. While calculating the degree of hydration of cement based on the thermogravimetric analysis, the traditional procedure was modified. The purpose of this study is not only to identify the effect of untreated and alkaline treated hemp powders on the hydration of cement paste, but also to find out the effect of replacement rate, treatment method, and hemp powder size on cement hydration. Moreover, the microstructure of cement paste without and with hemp powders was also examined.

2.2 Materials and Experiments

2.2.1 Hemp Powder Preparation

Hemp powders were prepared from flowering materials (flowers and leaves) and used to partially replace cement in this study. These flowering materials were provided by Green Remedy, Inc. (Louisville, KY, USA). Cannabidiol (CBD) was extracted from them prior to hemp powder preparation. To prepare the hemp powders, oven dried flowering materials (shown in Fig. 2.1(a)) were firstly chopped and blended into powders by using a high-speed blender and then sieved through a No. 200 sieve. The powders passing through

the sieve were called fine hemp powders, as shown in Fig. 2.1(b), and those retained on the sieve were called coarse hemp powders, as shown in Fig. 2.1(c).

Fig. 2.1. (a) hemp leaves; (b) fine hemp powders; and (c) coarse hemp powders.

2.2.2 Chemical Treatment

The fine and coarse hemp powders were chemically treated by using the same procedure as introduced below. Saturated calcium hydroxide solution (saturated lime water) with a concentration of 0.155% was prepared in a beaker at room temperature. Hemp powders were introduced to the prepared solution (hemp-to -solution mass ratio = 0.1) and stirred by using an AREX-6 Digital PRO (a kind of hot plate stirrer) (Velp Scientifica, Usmate, Italy) to assure good dispersion. The beaker was then covered to avoid water evaporation. After 24h, a centrifuge was used to filter out hemp powders from the calcium hydroxide solution. A part of treated hemp powders was collected without washing. The remaining part of the treated hemp powders was further washed by distilled water several times until the pH was close to neutral. The collected wet hemp powders (both washed and non-washed) were dried in an oven for 24h at 40 °C. And finally, the dried hemp powders were ground by using a mortar and pestle to eliminate the clumping. Based on the hemp

powder size and treatment method, six types of hemp powders were obtained, as listed in Table 2.1.

Table 2.1 Classification of hemp powders

Sample	Specification
RU	Untreated hemp powders retained on No. 200 sieve
PU	Untreated hemp powders passing through No. 200 sieve
RTN	Nonwashed treated hemp powders retained on No. 200 sieve
PTN	Nonwashed treated hemp powders passing through No. 200 sieve
RTW	Distilled-water-washed treated hemp powders retained on No. 200 sieve
PTW	Distilled-water-washed treated hemp powders passing through No. 200 sieve

Note: P=passing; R=retained; U=untreated; T=treated; N=nonwashed; and W=washed.

2.2.3 Cement paste preparation

The chemical compositions and the mineral clinker compounds of the Type I/II cement used are shown in Table 2.2 and

Table 2.3 (Shang and Sun 2019). The water/binder ratio was kept at 0.50, and hemp powders were used to replace 5.0% and 10.0% of cement by weight. The corresponding mix proportion is shown in Table 2.4. The samples are named after the hemp powder type and dosage. For example, RTW10 denotes the paste with 10% of cement replaced by distilled water washed treated hemp powders that were retained on the No. 200 sieve.

Table 2.2 Chemical composition of Type I/II low alkaline (LA) portland cement

Chemical compound	Weight (%)
CaO	63.30
SiO ₂	19.70
Al ₂ O ₃	5.00
Fe ₂ O ₃	3.47
MgO	3.59
SO ₃	2.50
Na ₂ O	1.55
K ₂ O	0.45
Loss on Ignition	0.54

Table 2.3 Major compounds of Type I/II LA portland cement

Clinker phase	Weight (%)
C ₃ S	59.32
C ₂ S	11.81
C ₃ A	7.39
C ₄ AF	10.55

Table 2.4 Mix proportions of cement paste

Sample	Water	Cement (Type I/II)	Hemp powder	Specification
Control	0.5	1	0	Cement paste with no hemp powders
PU5	0.5	0.95	0.05	Cement paste with 5% PU
RTN5	0.5	0.95	0.05	Cement paste with 5% RTN
PTN5	0.5	0.95	0.05	Cement paste with 5% PTN
RTW5	0.5	0.95	0.05	Cement paste with 5% RTW
PTW5	0.5	0.95	0.05	Cement paste with 5% PTW
PU10	0.5	0.90	0.10	Cement paste with 10% PU
RTN10	0.5	0.90	0.10	Cement paste with 10% RTN
PTN10	0.5	0.90	0.10	Cement paste with 10% PTN
RTW10	0.5	0.90	0.10	Cement paste with 10% RTW
PTW10	0.5	0.90	0.10	Cement paste with 10% PTW

Note: P=passing; R=retained; U=untreated; T=treated; N=nonwashed; W=washed; 5=5%; and 10=10%.

2.2.4 Isothermal Calorimetry Test

In order to evaluate the hydration of cement, Isothermal Calorimetry (IC) test was conducted on cement paste according to ASTM C1702 (ASTM. 2009). TAM Air (TA Instruments, New Castle, Delaware), a commercial calorimeter, was adopted in this study (Sun et al. 2017). It is an eight-channel isothermal heat conduction calorimeter with an operating temperature range of 5–60°C. Before the testing, the equipment was carefully calibrated based on the calibration procedures specified by the manufacturer's manual. The energy change during hydration was collected and registered by an automated data-acquisition program. The energy value was calculated based on the unit weight of cementitious materials' mass.

2.2.5 Thermogravimetric Analysis

Thermogravimetric analysis (TGA) was conducted on each type of hemp powders under nitrogen atmosphere with a flow rate of 40 ml/min from 25 °C to 600 °C, with a heating rate of 10 °C/min. Around 10 mg of hemp powders were used for each run. The purpose of this step was to study the decomposition of hemp powders within the temperature range and thus evaluate the effectiveness of calcium hydroxide treatment on the removal of hemicellulose.

TGA was also conducted on 7-day paste mixtures under nitrogen atmosphere, with a flow rate of 40ml/min from 25 °C to 1100 °C. The temperature profile includes increasing from room temperature to 105 °C by 20 °C/min and then keeping the temperature at 105 °C for 12h to remove the evaporable water in the sample. Subsequently, the sample was heated from 105 °C to 1100 °C by 20 °C/min, and then the temperature was kept at 1100 °C for 6h to extract all chemically bound water (CBW). Around 20 mg paste sample was used for each run. The TGA tests were also conducted on pure cement powder and each type of hemp powders by adopting the same test procedure in order to correct the weight loss between 105 °C and 1100 °C for chemically bound water calculation.

For cement paste without hemp powders, the calculation of chemically bound water (CBW) is regularly defined as the weight loss of the tested cement paste between 105 °C and 1100 °C, corrected for the loss on ignition (LOI) of the dry cement powder itself (Cao et al. 2015; Feng et al. 2004). However, for cement pastes with hemp powders, the calculation of chemically bound water is more complicated and needs to be additionally corrected to take account for the decomposition of hemp powders involved. In this study,

the detailed procedures of the CBW correction and the corresponding calculation of degree of hydration (DoH) for cement pastes with hemp powers are shown in the Appendix.

2.2.6 Fourier Transform Infrared Spectroscopy Analysis

Fourier transform infrared spectroscopy (FTIR) test was conducted on pure cement powder and 7-day cement pastes by using a PerkinElmer Spectrum 100[®] series spectrometer (Shelton, Connecticut). The sampling technique of Attenuated Total Reflection (ATR) was adopted to enable samples to be examined directly without further preparation (Elmer 2005). The background spectrum was collected at ambient atmosphere, and then the samples were directly analyzed. The spectra were recorded in the range of 650-4000 cm^{-1} with the resolution of 4 cm^{-1} (Horgnies et al. 2013). The purpose of the FTIR test is to evaluate the effect of hemp powders on cement hydration qualitatively by observing the change of functional groups of cement pastes.

2.2.7 Scanning Electron Microscopy Analysis

Scanning electron microscopy (SEM) analysis was conducted on the powdered cement pastes using NOVA NANOSEM 600[™] provided by FEI (Hillsboro, Oregon). Before testing, in order to suppress charging effect, gold sputtering was applied to the surface of specimens. While testing, the Everhart Thornley detector (ETD) in the secondary electron mode was adopted. The beam current and voltage were 0.32nA and 10kV, respectively. The purpose of SEM analysis is to observe the microstructure of cement pastes with hemp powders and then identify the effect of hemp powders on cement hydration.

2.3 Results and Discussions

2.3.1 Thermogravimetric Analysis on Hemp Powders

The TGA test has been applied to various types of hemp powders as listed in Table 2.1. The TGA results on fine hemp powders (PU, PTN, and PTW) and coarse hemp powders (RU, RTN, RTW) are shown in **Fig. 2.2(a)** and **Fig. 2.2(b)**, respectively. For each figure, the weight loss and the weight loss rate (denoted as derivative weight (%/min)) are plotted.

In both figures, it can be seen that there is a large weight loss between 200 and 300 °C, which is indicative of high hemicellulose content (Lv et al. 2010; Yang et al. 2007). Even a clear shoulder peak at 200-300 °C exists in DTGA curves for both figures, which is mainly attributed to the decomposition of hemicellulose (Wang et al. 2016). Between 200 and 300 °C, the weight losses of PU, PTN, and PTW are 22.53%, 17.35%, and 16.04%, respectively, and the weight losses of RU, RTN and RTW are 21.87%, 17.00% and 15.18%, respectively, as shown in **Table 2.5**. Compared to untreated hemp powders, for chemically treated hemp powders, the hemicellulose content decreases, and also the shoulder peaks in DTGA curves become less obvious. In addition, both PTW and RTW have much smoother DTGA curves at 200-300 °C than PTN and RTN. It can be attributed to the washing process after the chemical treatment that further removes hemicellulose. The weight loss of fine hemp powders is slightly more than that of the coarse hemp powders, which may be because fine hemp powders with the larger specific surface area are much easier to be decomposed than coarse hemp powders.

From both figures, a significant peak can be seen between 300 and 400 °C on the derivative weight curve, which is mainly due to the decomposition of cellulose (Yang et al.

2007). In this temperature range, the weight losses of PU, PTN, and PTW are 18.68%, 21.12% and 23.40%, respectively, and the weight losses of RU, RTN and RTW are 19.03%, 23.92% and 26.25%, respectively, as shown in **Table 2.5**. It can be seen that the weight loss of cellulose correlates to the weight loss of hemicellulose. That is because chemical treatment and washing process remove some hemicellulose, resulting in the increased relative content of cellulose.

Bilba et al. reported that hemicellulose could be decomposed into saccharides in an alkali medium that can have a negative impact on cement hydration (Bilba et al. 2003). The TGA results indicate that the chemical treatment and the further washing process can assist the removal of hemicellulose, which is helpful to minimize the set delay effect of the hemp powders. By comparison of the weight losses, it is expected that the descending order of set delay effect is PU, PTN, and PTW for fine hemp powders, and RU, RTN, and RTW for coarse hemp powders. In addition, the set delay effect on the hydration of RU, RTN, and RTW is expected to be less than that of PU, PTN, and PTW, respectively, due to the smaller specific surface area.

Table 2.5 Weight loss (W_L) of all types of hemp powders

Sample	W_L (%)	
	200-300 °C	300-400 °C
PU	22.53	18.68
PTN	17.35	21.12
PTW	16.04	23.40
RU	21.87	19.03
RTN	17.00	23.92
RTW	15.18	26.25

2.3.2 Isothermal Calorimetry and Thermogravimetric Analysis on Cement Pastes

Based on the calorimetric analysis, the heat evolution and heat evolution rate during hydration of Portland cement pastes without and with hemp powders are shown in **Fig. 2.3(a)** and **Fig. 2.3(b)**, respectively. The hydration time corresponding to the peaks in **Fig. 2.3(b)** is listed in **Table 2.6**. The degree of hydration (DoH) of 7-day cement paste is calculated according to the procedure introduced in the Appendix and summarized in **Fig. 2.4**.

From **Fig. 2.3(b)**, two peaks next to each other (corresponding to C_3S (the 1st peak from the left side) and C_3A hydration (the 2nd peak), respectively) of the control sample can be clearly seen; however, for any other sample, the second peak disappears, showing the C_3A hydration and ettringite conversion are much affected. This may be because saccharides from hemp powders prevent the formation of ettringite. It has been reported that saccharides influence the morphological evolution of hydrating aluminate particles, such as C_3A (Smith et al. 2011). Moreover, the microstructure analysis introduced in this study shows the formation of needle-like ettringites is much influenced by hemp powders.

Compared to the control, **Fig. 2.3(a)** and **Fig. 2.3(b)** show that the heat evolution and heat evolution rate of other samples with hemp powders are all reduced, and **Table 2.6** shows that the hydration time corresponding to the maximum peak of heat evolution rate curve increases (except for PU10 and PTN10). That indicates the addition of hemp powders in cement delays the hydration, which is supported by the reduced degree of hydration (DoH) at 7 days as shown in **Fig. 2.4**. For PU10 and PTN10, the heat evolution amount (**Fig. 2.3(a)**) is very low, and no peaks exist in their heat evolution rate curve (**Fig. 2.3(b)**). The calculated DoH values shown in **Fig. 2.4** are very small. When 10% of the cement powder is replaced, the delay effect of hemp powders is so significant that the dormant period of the samples is very much extended.

The delay effect of hemp powders on cement hydration could be mainly due to the fact that some saccharides are possibly leached out (Vaickelionis and Vaickelioniene 2006). The delaying mechanism of saccharides for cement hydration has not been identified clearly, however, some possible reasons are proposed. One reason is that saccharides can form a complex with the metal ions present in the cement through chelation (Chakraborty

et al. 2013). A protective layer around the partially reacted cement grain is formed to prevent further hydration of cement, which can delay the nucleation and the growth of the hydrated products (Jo and Chakraborty 2015). The second reason may be that some saccharides are unstable in cement paste and can be degraded into some sugar acids, which can inhibit cement hydration (Kochova et al. 2017). The third possible reason can be that organic retarders have strong calcium binding capacity that can prevent the formation of calcium-silicate-hydrate (C-S-H) (Kochova et al. 2017).

Fig. 2.4. Degree of hydration of 7-day cement paste samples.

2.3.3 The Effect of Replacement Content on Cement Hydration

In this study, 5% and 10% hemp powders were used to replace cement, respectively. Since for cement pastes with any type of hemp powders, the effect of replacement content on cement hydration is similar, RTN incorporated cement pastes are taken as an example for analysis. The heat evolution and heat evolution rate of RTN incorporated cement paste

with different replacement contents are shown in **Fig. 2.5(a)** and **Fig. 2.5(b)**, respectively. It can be noted that compared to RTN5, the heat evolution and heat evolution rate of RTN10 is lower. Also, Table 2.6 and Fig. 2.4 show that with the increase of replacement content, the hydration time corresponding to the maximum peak of heat evolution rate curve increases, and the DoH value decreases. This is not only because higher replacement content can dilute cement and thus undoubtedly reduce the heat evolution, but also more hemp powders can be possibly decomposed to generate more saccharides in cement paste, inhibiting cement hydration.

Fig. 2.5. (a) Heat evolution; and (b) heat evolution rate during hydration of RTN-incorporated cement paste.

2.3.4 The Effect of Treatment Method on Cement Hydration

In this study, different treatment methods were applied to hemp powders. The cement pastes with 5% fine hemp powders are taken as an example for analysis. **Fig. 2.6(a)** and **Fig. 2.6(b)** plot the heat evolution and heat evolution rate of the pastes with 5% fine hemp powders, respectively. PTN5 and PTW5 both have higher heat evolution amount and heat evolution rate than those of PU5, and PTW5 has the highest amount among the three. Moreover, the hydration time corresponding to the maximum peak of the heat evolution

rate curve is reduced, and the corresponding DoH value is improved, as shown in Table 2.6 and Fig. 2.4, respectively. This indicates that compared to untreated hemp powders (PU), the addition of treated hemp powders (PTN or PTW) to cement paste can mitigate the delay effect on the hydration of cement. The reason can be after calcium hydroxide treatment, much hemicellulose, lignin, and other extractives that can be decomposed into saccharides are removed from hemp powders (Lu and Oza 2011; Sawpan et al. 2011). This is also confirmed by the TGA test on hemp powders in this research. Compared to non-washed treated hemp powders (PTN), the washing process after chemical treatment can further mitigate the delay effect on the hydration of cement, resulting in a higher degree of hydration for washed treated hemp powders (PTW). This can be attributed to the further removal of hemicellulose during the washing process. This can also be due to the removal of some remaining saccharides during washing.

Fig. 2.6. (a) Heat evolution; and (b) heat evolution rate during hydration of portland cement paste with 5% fine hemp powders.

2.3.5 The Effect of Hemp Powder Size on Cement Hydration

To study the size effect, cement pastes with 10% washed treated hemp powders are compared. The heat evolution and heat evolution rate of Portland cement paste with 10%

washed treated hemp powders is shown in **Fig. 2.7(a)** and **Fig. 2.7(b)**, respectively. It can be seen that compared to RTW10, PTW10 can lower the heat evolution amount and heat evolution rate. Moreover, Table 2.6 and Fig. 2.4 demonstrate that PTW10 has an increased hydration time corresponding to the maximum peak of the heat evolution rate curve and a lower DoH value, respectively. This indicates that the addition of fine hemp powders (PU, PTN, and PTW) can intensify the delay effect on the hydration of cement compared to coarse hemp powders (RU, RTN, and RTW). The possible reason may be that finer hemp powders (PU, PTN, and PTW) have higher specific surface area than coarse hemp powders (RU, RTN, and RTW), and they can be much easier to be dissipated in cement paste to produce saccharides, delaying the hydration of cement.

Fig. 2.7. (a) Heat evolution; and (b) heat evolution rate during hydration of portland cement paste with 10% washed treated hemp powders.

2.3.6 FTIR Analysis on Cement Pastes

The FTIR spectra of original Portland cement (OPC) and hydrated cement pastes at 7 days are shown in **Fig. 2.8**. There are four important regions that include water region ($>1600 \text{ cm}^{-1}$), carbonate region ($1400\text{--}1450 \text{ cm}^{-1}$), sulfate region ($1100\text{--}1150 \text{ cm}^{-1}$), and

silicate region ($<1000\text{ cm}^{-1}$) (Mollah et al. 2000). The FTIR spectral data of each region are shown in **Table 2.7**.

Water region

From **Fig. 2.8(a)**, it is shown that for OPC, there are no significant peaks in the water region. However, for all hydrated cement pastes (**Fig. 2.8(b-l)**), three important peaks appear in this region, and the corresponding spectral data are shown in **Table 2.7**. The first peak appears between 3612 and 3645 cm^{-1} , which corresponds to the OH band from Ca(OH)_2 (Mollah et al. 2000; Ylmén et al. 2009). This is attributed to the hydration of C_3S and C_2S . The second peak appears between 3409 and 3435 cm^{-1} , which corresponds to hydrogen-bonded OH species (OH–OH) adsorbed on the surfaces (Mollah et al. 2000). This is due to the symmetric and asymmetric stretching vibration (ν_1 and ν_3) of H_2O in the hydrated cement paste (Chakraborty et al. 2013; Choudhary et al. 2015; Ylmén et al. 2009). The third peak appears between 1641 and 1670 cm^{-1} , which may be attributed to the bending vibration ν_2 of water in sulphates, mainly gypsum (Ylmén et al. 2009).

Carbonate region

For OPC, **Fig. 2.8(a)** does not show any significant peaks in the carbonate region. However, for all hydrated cement pastes (**Fig. 2.8(b-l)**), a peak between 1416 and 1425 appears, which is due to the reaction of atmospheric CO_2 with the calcium hydroxide produced by cement hydration (Liu and Sun 2013).

Sulfate region

The sulfates present in OPC are gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), hemihydrate ($\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$) and anhydrite (CaSO_4), and the sulfate region in FTIR spectrum is located between 1100 - 1150 cm^{-1} , corresponding to the ν_3 vibration of the SO_4^{2-} group in sulphates

(Choudhary et al. 2015; Ylmén et al. 2009). **Fig. 2.8(a)** shows that two peaks (1143 cm^{-1} and 1126 cm^{-1} listed in **Table 2.7**) appear in the sulfate region of OPC, which may be because different forms of sulfates lead to different peaks. Upon hydration, these two peaks become one peak that is between 1114 and 1120 cm^{-1} for all hydrated cement pastes, as shown in **Fig. 2.8(b-l)** and **Table 2.7**. The shift of sulfate band towards a lower wavenumber is due to the formation of ettringite (Mollah et al. 2000).

Silicate region

Fig. 2.8(a) shows that OPC has a significant peak at 917 cm^{-1} in the silicate region, which is due to Si–O asymmetric stretching vibration (ν_3) of C_3S and C_2S phase (Choudhary et al. 2015). For hydrated cement pastes (except for PU10 and PTN110), this peak significantly shifts towards a higher wavenumber that is between 954 and 965 cm^{-1} as shown in **Table 2.7**. The shifting of the Si–O stretching vibration is indicative of the polymerization of silicate units (SiO_4^{2-}), with the formation of C–S–H phase as a result of cement hydration (Govin et al. 2006; Mollah et al. 2000; Peschard et al. 2004). However, **Fig. 2.8(h)** shows the silicate peak of PU10 does not shift and **Fig. 2.8(i)** shows the peak of PTN10 only shifts 6 cm^{-1} , which may be because the degree of hydration for these two samples is so low that very few C–S–H is formed. This is confirmed by IC and TGA tests that PU10 and PTN10 are still in the dormant period after 7 days.

Fig. 2.8. FTIR spectra of (a) OPC; (b) control; (c) PU5; (d) PTN5; (e) PTW5; (f) RTN5; (g) RTW5; (h) PU10; (i) PTN10; (j) PTW10; (k) RTN10; and (l) RTW10.

Table 2.7 FTIR spectral data for original portland cement and hydrated cement pastes

Samples	Water region			Carbonate region	Sulfate region	Silicate region
	Peak 1	Peak 2	Peak 3	Peak 1	Peak 1	Peak 1
OPC	—	—	—	—	1143 & 1126	917
Control	3644	3419	1641	1424	1118	962
PU5	3643	3422	1650	1420	1119	961
PTN5	3644	3419	1648	1424	1117	960
PTW5	3644	3419	1658	1420	1120	965
RTN5	3644	3427	1657	1425	1115	961
RTW5	3645	3418	1649	1420	1118	964
PU10	3626	3409	1670	1424	1114	917
PTN10	3612	3414	1653	1419	1114	923
PTW10	3645	3435	1655	1422	1115	964
RTN10	3645	3423	1650	1421	1114	954
RTW10	3645	3419	1643	1416	1114	959

Note: M—dashes indicate no peak.

2.3.7 Microstructure

In order to examine the effect of untreated and chemically treated hemp powders on the microstructure of cement paste, the control, PU10, PTN10, and PTW10 samples at 7 days are taken as an example for analysis. In addition, the SEM image on unhydrated cement powders is also adopted to assist analysis. For unhydrated cement powders, some large irregular particles can be clearly seen, as shown in **Fig. 2.9(a)**. For the control cement paste, **Fig. 2.9(b)** shows that some needle-like ettringites and C-S-H are formed after cement hydration. For PU10, some large unhydrated cement particles and rod-like ettringites can be seen in **Fig. 2.9(c)**. This could be due to large amounts of decomposition products (most possibly much saccharides) of untreated hemp powders delaying the hydration of cement, as confirmed by TGA and IC tests in this study. Moreover, the seriously delayed cement hydration prevent the further development of rod-like ettringites into needle-like ettringites. It has been reported that at a very early stage, ettringites are formed as hexagonal rods, and the relatively slender ettringites can be observed with the hydration progress (Liu 2014). Also, Cody et al. reported that the presence of sugars can lead to the morphology of ettringites to be short thick hexagonal prisms rather than needles (Cody et al. 2001). For PTN10, many unhydrated cement particles are clearly shown in **Fig. 2.9(d)**. Compared to PU10, PTN10 has some small needle-like ettringites instead of rod-like ettringites on the surface, which indicates that some needle-like ettringites start to form. The reason may be chemically treated hemp powders have fewer saccharides inside, which makes the hydration of cement less delayed. For PTW10, although a small quantity of unhydrated cement particles can still be identified, they are not obvious in **Fig. 2.9(e)**.

Compared to PU10 and PTN10, more hydration products are formed, and the hydration of PTW10 seems to be the least delayed.

2.4 Conclusions

In this research, untreated and calcium hydroxide treated hemp powders were used to partially replace cement. Compared to pure cement paste, IC test shows that the incorporation of hemp powders in cement paste can reduce heat evolution amount and slow down heat evolution rate; also, the degree of hydration (DoH) calculated based on TGA test matches the IC results. This confirms the delaying effects of hemp powders on cement hydration. SEM analysis shows that the formation of hydration products are significantly influenced if hemp powders involved.

The research also shows that the 10% replacement content (by weight of cement) delays the hydration of cement significantly. Particularly, for PU10 (untreated fine powders) and PTN10 (treated but non-washed fine powders) samples, the hydration is almost completely inhibited, and the degree of hydration is significantly low compared to others (e.g. 5% replacement by weight of cement). This indicates that 10% is the limit replacement if hemp powders are used. If the volume fraction of aggregates in concrete is assumed as 60%-80% and the specific gravity of hemp powder is approximately assumed as 1, the dosage limit of hemp powders by volume of concrete will be calculated as 2.24%-4.48% (10% dosage limit by weight of cement).

Compared to the pastes with untreated hemp powders, treated hemp powders can reduce the delay effect when used. Also, the washed treated hemp powders had the minimum delay effect on cement hydration. The reduced delay effect may be attributed to

the fact that much hemicellulose is removed after calcium hydroxide treatment and washing process, as confirmed by TGA test in this study.

In addition, the study also shows that fine hemp powders can delay the hydration of cement paste more than coarse hemp powders, which can be attributed to the higher specific surface area of fine hemp powders that can be easily decomposed into saccharides to delay the hydration of cement.

Generally, regardless of replacement content, treatment method, and hemp powder size, the delaying effect of hemp powders on cement hydration is obvious, which can possibly reduce the mechanical properties of cementitious materials significantly. However, hemp powders can be useful in serving as powder-type retardation agents to adjust cement hydration rate as needed, particularly in some extreme occasions where rapid hydration needs to be avoided.

CHAPTER 3 IMPACT OF THERMALLY MODIFIED WOOD ON MECHANICAL PROPERTIES OF MORTAR

3.1 Introduction

In addition to the lignocellulosic powders introduced in Chapter 2, some lignocellulosic biomass wastes exist in the form of chips with a larger size than powders. They are appropriate to partially replace sand in cementitious materials due to the similar size. However, similar to powders, some components (hemicellulose, lignin, and extractives) of lignocellulosic chips can be degraded under alkali condition, which can not only delay cement hydration but also negatively affect the bonding with cementitious matrix and thus deteriorate the mechanical properties of cementitious composites (Vo and Navard 2016). To mitigate degradation and debonding, lignocellulosic chips need to be modified. Thermal treatment as a physical treatment method has been shown to improve the mechanical properties of lignocellulosic biomass-cement composites (Wei and Meyer 2014). This is because some undesirable components of lignocellulosic biomass can be removed at a higher temperature when they start to degrade (Kabir et al. 2012).

In this chapter, softwood chips were torrefied under high (260 °C) and low (220 °C) temperatures, respectively. Different substitution amounts (5% and 10% by weight of sand) of the wood chips were used in mortars. Flowability, compressive strength, flexural strength, modulus of elasticity, and the toughness of mortars were investigated. The

purpose of this study is to identify the effect of the addition of waste ground wood chips on mortar and the possibility of the torrefaction treatment of ground wood chips to positively affect mortar in terms of mechanical properties.

3.2 Materials and Experiments

3.2.1 Ground Wood Preparation

Three types of waste ground wood chips were used in this study. They are named as the original wood chip (OW, non-torrefied), highly torrefied wood chip (HTW), and lightly torrefied wood chip (LTW), as shown in **Fig. 3.1**.

Fig. 3.1. Wood chips: (a) OW; (b) HTW; (c) LTW

OW is from softwood pine, and its properties is shown in **Table 3.1** (Peng et al. 2013). HTW and LTW were obtained by torrefaction treatment under the corresponding temperature of 260 °C and 220 °C, respectively, for 20-60 minutes.

Table 3.1 Properties of pine

Properties		Value (%)
Chemical composition	Cellulose	36.7
	Hemicellulose	26.3
	Lignin	33.6
Elemental analysis	Carbon	51.2
	Hydrogen	6.0
	Oxygen	42.2
	Nitrogen	0.1
Proximate analysis	Volatile matter	82.8

Fixed carbon	16.8
Ash	0.4

The size of the waste ground wood chips was made according to the ASTM standard sand as specified by ASTM C778 (Standard 2012), and were prepared by passing through the No.20 (850 μ m) sieve and retaining on the No.30 (600 μ m) sieve.

In order to study the influence of torrefaction treatment on removal of hemicellulose, lignin, and other impurities, thermogravimetric analysis was conducted on all three waste wood chips (shown in **Fig. 3.2**). During the test, SDT Q600 (by TA Instruments) was used with the sample size of about 10mg in each test. The temperature was set to increase from room temperature (around 25°C) to 300 °C with the rate of 10 °C/min. The change in the sample weight was continuously monitored during the test. **Fig. 3.2** shows that the weight losses from 100 °C to 220 °C are found to be around 1.40% (OW), 1.00% (HTW), and 1.20% (LTW), which indicates that wood chips degrade slightly at 220 °C. From 220 °C to 260 °C, the weight losses are around 2.00%, 0.70%, and 1.60%, which indicates that certain amounts of substances degrade at 260 °C. By comparison, the descending order of the weight loss is OW, LTW, HTW. The lower weight loss indicates more substances have been removed from wood chips in the process of torrefaction treatment. It has been reported that the pyrolysis of lignin can happen slowly under a temperature range from 150 to 900 °C; the pyrolysis of hemicellulose and cellulose can occur at 220-315°C and 315-400 °C, respectively (Yang et al. 2007). Therefore, the weight loss from 100 °C to 260 °C is mainly attributed to the pyrolysis of lignin and hemicellulose. By torrefaction treatment, some hemicellulose and lignin are removed for LTW, and higher amounts of both lignin and hemicellulose are removed for HTW. It has been reported that the presence of hemicellulose and lignin in fibers will negatively affect the mechanical

properties of fiber reinforced concrete (Vo and Navard 2016). Therefore, in this study, the decrease in lignin and hemicellulose in thermal treated chips can contribute positively to mortar.

Fig. 3.2. Thermogravimetric analysis on OW, HTW, and LTW

Fourier transform infrared spectroscopy (FTIR) test was conducted by using spectrum 100 series spectrometer to study the effect of torrefaction temperature on the components of wood chips by examining the change of functional groups. The spectra were recorded in the range of $650\text{--}4000\text{ cm}^{-1}$ with the resolution of 4 cm^{-1} , and the FTIR curve is shown in **Fig. 3.3**. The peak at “a” represents O-H group indicating large amounts of hydroxyl groups in wood chips. The peak of O-H group decreases with the increase of torrefaction temperature, and the similar conclusion was obtained by Mei et al. (Mei et al. 2016). This may be attributed to the dehydration of wood chips, and more and more water are removed with the increase of torrefaction temperature (Chen et al. 2015; Chen et al. 2012). The peak at “b” represents C-H group indicating the presence of alkanes (Gao et al. 2012), which is attributed to the aliphatic fractions of wax (Shang et al. 2012). With the increase of torrefaction temperature, more and more C-H groups are broken (Chen et al. 2012; Mei et al. 2016). The decomposition of wax from wood chips can contribute to its

strength (Andiç-Çakir et al. 2014), which can be expected to be conducive to the mechanical properties of mortar. The peak at “c” represents C=O group indicating the existence of ketones and aldehydes (Gao et al. 2012; Mei et al. 2016), which is due to carboxyl groups in cellulose and hemicellulose (Chen et al. 2015; Shang et al. 2012). For torrefied wood chips, this peak decreases in intensity, which is in good agreement with the previous studies (Chen et al. 2015; Chen et al. 2012). The decrease of this peak may be mainly because some hemicellulose can be decomposed under thermal treatment, as evidenced by TGA test. The peak at “d” represents C=C group indicating aromatic ring skeleton vibrations (Gao et al. 2012). With the increase of torrefaction temperature, the peak increases, which is because torrefaction treatment results in the cleavage of ether bond in lignin and the condensation of lignin by linking carbons directly (Park et al. 2013). Chang et al. conducted FTIR test and concluded that the carbohydrate (mainly hemicellulose) decomposition predominates over lignin decomposition after torrefaction treatment (Chang et al. 2012). In general, FTIR test confirms the decomposition of hemicellulose, lignin, and wax caused by torrefaction, which will be beneficial to the mechanical properties of mortar.

Fig. 3.3. FTIR chart of OW, HTW, and LTW

3.2.2 Mortar Sample Preparation

Ground waste wood chips (shown in section 3.2.1), type I/II Portland cement (see Table 2.2 and

Table 2.3 (Shang and Sun 2019)), silica sand (ASTM C778), and tap water were used. In order to study the feasibility of using the proposed waste wood chips in concrete, wood chips were used to replace 5 % and 10 % of the silica sand (by weight). Seven different samples were made and studied (listed in **Table 3.2**).

Table 3.2 Prepared mortar samples

Designation	Wood chip type	Mix proportion			
		Water	Cement	Sand	Ground wood
Control	–	0.5	1	2.25	–
W05	OW	0.5	1	2.1375	0.1125
H05	HTW	0.5	1	2.1375	0.1125
L05	LTW	0.5	1	2.1375	0.1125
W10	OW	0.5	1	2.025	0.225
H10	HTW	0.5	1	2.025	0.225
L10	LTW	0.5	1	2.025	0.225

Two different mixing procedures were used based on the presence of ground wood chips. For plain mortar (without ground wood chips), sand and cement were dry mixed for 1 minute and then water was added to mix for 3 minutes. The mixture was then left alone for 2 minutes, and then continued to mix for another 3 minutes. For mortar with ground wood chips, the sand and the wood chips were mixed first for 1 minute; And the cement was added to the mix for another 1 minute. After introducing water to the dry mix, the mixing procedure used for plain mortar was followed. 2×2×2in cubes and 1×1×10in beams were cast following series of experiments. The specimens were sealed for the first 24 hours and then were demolded. The calculated density, bulk density, and porosity of mortars were shown in **Table 3.3**. The mortar samples were kept in a moisture room with 100% humidity and 22°C till testing.

Table 3.3 Basic parameters of mortar samples

Designation	Wet bulk density (g/cm ³)	Calculated Density (g/cm ³)	Porosity (%)
Control	2.23	2.25	0.9
W05	1.78	2.21	19.28
W10	1.72	2.16	20.44
H05	1.98	2.20	10.14
H10	1.86	2.16	13.83
L05	1.99	2.20	9.69
L10	1.93	2.16	10.59

3.2.3 Flowability Test

Flowability test provides information about the workability of mortar. A flow table was used in the test, and the flowability test was conducted according to the procedures specified in ASTM C1437 (ASTMC1437-13). Based on the original base diameter and the diameter of mortar pie after tamping, flowability can be calculated using Eq. (3.1):

$$Fl = \frac{A' - A}{A} \times 100\% \quad (3.1)$$

where Fl is flowability; A is the original base diameter (100 mm); A' is diameter of mortar pie after tamping.

3.2.4 Mechanical Tests

3.2.4.1 Compressive Test

A universal testing machine and 2×2×2in cubes were used for compressive test. Based on the maximum load (F) obtained from this test, compressive strength is calculated using Eq. (3.2):

$$\sigma_c = \frac{F}{A} \quad (3.2)$$

where σ_c is compressive strength; F is maximum load; A is cross area of a cube (2×2 in²).

3.2.4.2 Flexural Test

Flexural strength is one way to characterize tensile strength. In this study, a universal testing machine and 1×1×10in beams were used. A testing configuration can be seen in **Fig. 3.4(a)**. From the flexural test, a typical load-deflection curve can be obtained directly, as shown in **Fig. 3.4(b)**. Based on the maximum load from flexural test, flexural strength is calculated using Eq. (3.3):

Fig. 3.4. Testing configuration (a) and typical load-deflection curve (b) of flexural test

$$\sigma_f = \frac{3FL}{2bh^2} \quad (3.3)$$

where σ_f is flexural strength; F is maximum load; L is length of a beam; b is width of a beam; h is height of a beam.

Based on the load-deflection curve from flexural test, the data between 10% F and 40% F are fitted into a straight line. Then, the slope of the fitted straight line can be obtained, by which the static modulus of elasticity is calculated using Eq. (3.4):

$$E_s = \frac{ml^3}{4bh^3} \quad (3.4)$$

where E_s is static modulus of elasticity; l is length of a beam; m is slope of the fitted straight line; b is width of a beam; h is height of a beam.

In order to observe energy absorption capacity and the post-peak behavior of the samples, flexural toughness (*FT*) and toughness index (*TI*) were further calculated based on the flexural test. *FI* is defined as the ratio between the absorbed energy during flexural test and area of the broken section, and *TI* is defined as the ratio between area under the load-deflection curve and area under the curve up to maximum load (Chakraborty et al. 2013; Li et al. 2006). The area under the load-deflection curve represents the absorbed energy during flexural test.

3.2.4.3 Resonance Frequency Test

1×1×10in beams were used for resonance frequency test to obtain the dynamic modulus of the specimen. This helps to understand the influence of ground wood chips on the elastic behavior of the mortar. The dynamic modulus of elasticity (E_d) can be calculated using Eq. (3.5) (ASTM 2008).

$$E_d = DMn^2 \quad (3.5)$$

where E_d is dynamic modulus of elasticity; M is mass of specimen, kg; n is fundamental longitudinal resonance frequency, Hz; D is $4(L/bt)$; L is length of specimen, m; t and b are dimensions of cross section of specimen, m.

3.2.5 SEM Imaging

Scanning electron microscopy (SEM) is used to study the microstructure of ground wood chips and mortar. VEGA3 provided by TESCAN and NOVA NANOSEM 600 provided by FEI are used for this purpose.

In this study, sputtering was applied to the surfaces of specimens before testing. Mortar specimens with the thickness of 0.5mm were prepared. They were first polished by using sand paper and then cleaned by using ultrasonic bath before gold coating. Secondary

electron detector at 20kV was used to observe the surfaces of ground wood chips. Secondary electron detector at 5kV was used to observe the polished surfaces of mortar and mainly examine the area around wood chips, namely the wood chip-matrix interface.

3.3 Results and Discussions

3.3.1 Flowability

The Flowability of the tested mortars is shown in **Table 3.4**. Compared to the control sample, mortar with ground wood chips has much lower flowability, especially for those with 10% replacement level. It was also reported that the addition of natural fibers in mortar can decrease the flowability of mortars; also, the flowability decreases with the increase of fiber content (Chakraborty et al. 2013; Dawood and Ramli 2012). The decrease of flowability in this research is due to the fact that wood chips can absorb some water, resulting in less water available for mortar to flow (Çomak et al. 2018). Another reason may be the irregular particles of wood chips lead to decreased flowability. This experiment indicated that the flowability is acceptable if 5% sand is replaced with ground wood chips; however, when the replacement level is increased to 10%, admixtures, such as superplasticizer, is needed to achieve the desirable flowability.

Table 3.4 Flowability of mortar

Designation	Flowability (%)
Control	130±2
W05	92±3
W10	9±1
H05	86±1
H10	18±1
L05	82±2
L10	8±1

3.3.2 Compressive and Flexural Strength

The compressive strength and flexural strength of mortars are shown in **Fig. 3.5** and **Fig. 3.6**, respectively. Compared to the control, the compressive strength and flexural strength of all the composite mortars decrease significantly. The decrease of strength in this study may be attributed to the bonding between wood chips and the mortar matrix, which will be clarified in detail in following sections. Similar conclusion was obtained by Gil et al. who attributed the decrease of the compressive strength of mortar to a poor adhesion at the interfacial face (Gil et al. 2017). In general, mortars with HTW or LTW (except for L10) have higher compressive strength and flexural strength than mortars with OW. In this study, several reasons can be responsible for the improvement of mechanical properties: (1) heat treatment can eliminate the organic components, such as the water soluble sugar within fibers (Sellami et al. 2013); (2) thermal treatment can improve the crystallization of cellulose (Wei and Meyer 2014); (3) another possible reason may be the relative smooth surface of OW as compared to HTW or LTW, resulting in weak bonding between wood chips and mortar.

From **Fig. 3.5** and **Fig. 3.6**, it is shown that for mortars with 10% HTW or OW, the compressive and flexural strengths exhibit comparable or better values than those with 5%. However, for L10, its compressive strength and flexural strength are both significantly lower than those of L05. The reason may be the occurrence of alkaline hydrolysis, which will generate much saccharides retarding the hydration of cement (Chakraborty et al. 2013; Jo and Chakraborty 2015; Kochova et al. 2017). In case of LTW, the external surface is damaged by torrefaction as confirmed by SEM; in addition, even if all these three kinds of wood chips have the same size range, LTW used in this study has more finer chips than the

others. This will make LTW more easily contact with alkaline solution and thus is more prone to alkaline hydrolysis, which will deteriorate the strength of mortar by means of affecting the hydration of cement. For L05, because a small amount of LTW is used, the strength of mortar is not largely reduced; for L10, too much LTW reduced the strength significantly.

Also, by comparison, for all the mortars, it's shown that flexural strength decreased around 30-40%, which is less than the reduction amount of compressive strength (around 50-70%). It can be concluded that the application of ground wood chips in mortar will deteriorate the compressive strength more than flexural strength.

Fig. 3.5. Compressive strength of mortar samples (error bar is from standard deviation, which is applicable to all related figures in this study)

Fig. 3.6. Flexural strength of mortar samples*

*Note: For L10, 1-day beam was very weak and almost has no flexural strength. It's very hard to get 1-day flexural strength accurately. The reason applies to Fig. 3.7 through Fig. 3.10 with missing data.

3.3.3 Static and Dynamic Modulus of Elasticity

The static modulus of elasticity and dynamic modulus of elasticity are shown in **Fig. 3.7** and **Fig. 3.8**, respectively. Compared to the control, the static and dynamic modulus of elasticity of mortars with ground wood chips decrease significantly. This is similar to the results reported by other researchers [3, 36]. In this study, mortars with HTW or LTW (except for L10) have higher static and dynamic modulus than mortar with OW. L05 has good static and dynamic moduli; however, L10 has the lowest static and dynamic modulus. All these results here are consistent with those obtained for strength, and the reasons remain the same.

The relationship between dynamic modulus and static modulus has been investigated by many researchers. Diógenes et al. suggested that the dynamic modulus is usually 20, 30 and 40 percent higher than the static modulus (Diógenes et al. 2011). In this

study, by comparison, for most cases, the dynamic modulus of elasticity is 30-90% higher than the static modulus of elasticity.

Fig. 3.7. Static modulus of elasticity of mortar samples

Fig. 3.8. Dynamic modulus of elasticity of mortar samples

3.3.4 Toughness

The flexural toughness and toughness index are shown in **Fig. 3.9** and **Fig. 3.10**, respectively. Compared to the reference, mortars with ground wood chips have at least comparable or higher flexural toughness and toughness index, indicating better energy absorption capacity and post-peak behavior. Also, for most cases, toughness index and flexural toughness increase with the increase of ground wood chips. Therefore, mortar will

be more ductile by using ground wood chips in mortar. This is similar to the findings by Chakraborty et al. and Li, et al. who concluded that flexural toughness and toughness index could be increased with the incorporation of jute fibers or coir fibers in mortar (Chakraborty et al. 2013; Li et al. 2007). The reason may be attributed to the ability of arresting cracks of wood chips at micro- and macro- levels that leads to a more ductile failure mode with higher toughness (Elsaid et al. 2011).

Mortar with OW has higher flexural toughness and toughness index than mortar with HTW or LTW. This may be attributed to much weaker bonding between OW and mortar. In view of this, it is a good practice to use OW rather than HTW or LTW to enhance energy absorption capacity and post-peak behavior at the expense of strength.

Fig. 3.9. Flexural toughness of mortar samples

Fig. 3.10. Toughness index of mortar samples

3.3.5 Microstructure

The SEM imaging observation of the surface texture of ground wood chips is shown in **Fig. 3.11**. **Fig. 3.11(a)** shows that the surface of OW remains intact and seems to be smooth. However, **Fig. 3.11(b)** and (c) show that the surfaces of HTW and LTW after torrefaction become much rougher. This is attributed to decomposition of some components of OW. It can be confirmed by the results from TGA test that lignin will be decomposed for LTW, and both lignin and hemicellulose will be decomposed for HTW.

Fig. 3.11. Surface texture of (a) OW; (b) HTW; (c) LTW

The SEM images on mortar with ground wood chips are shown in Figs. 3.12-3.14. From **Fig. 3.12(a)**, the interface between matrix and OW can be clearly seen; however,

from **Fig. 3.13(a)** and **Fig. 3.14(a)**, the matrix and HTW or LTW combines well and the interface is not so clear. This can be attributed to the fact that HTW and LTW have much rougher surface texture than OW, which result in better bonding. That is why the compressive strength, flexural strength, static modulus of elasticity, and dynamic modulus of elasticity of HTW and LTW are higher than those for OW. As reported by Coutts, strong bonding between fiber and matrix results in a brittle material with high strength; however, a weak bonding results in a tough material lacking strength (Coutts and Kightly 1984). Therefore, compared to HTW and LTW, mortar with OW has higher flexural toughness and toughness index.

Some particular areas, marked by red circle, on the interfaces in Figs. 3.12(a), 3.13(a), and 3.14(a) are magnified, as shown in Figs. 3.12(b), 3.13(b), and 3.14(b), correspondingly. From Figs. 3.12(b), 3.13(b), and 3.14(b), it's shown that the interfaces between matrix and wood chips are loose, and even some cracks exist on the interfaces, which will decrease the mechanical properties of mortar. Therefore, the mechanical properties of mortar with ground wood chips become worse as compared to mortar without ground wood chips. But one advantage is that the toughness of mortar with ground wood chips improves. As reported by Toledo that a weak matrix in the vicinity of fiber can yield or crack, which can be favorable to the ductility (Toledo Filho et al. 2000). At micro-level, fibers inhibit the initiation of cracks; at macro-level, fibers provide effective bridging and impart sources of toughness and ductility (Dawood and Ramli 2010).

(marked by black ellipse)

3.4 Conclusions

In this study, ground wood chips were used to partially replace sand in mortar. Several important properties including flowability, and mechanical properties, etc. are investigated.

Because wood chips absorb large amounts of water resulting in less water available for mortar to flow, mortar with wood chips has lower flowability as compared to the reference. The flowability is acceptable if 5% (by weight) sand is replaced with ground wood chips; however, admixtures, such as superplasticizer, is needed to achieve the desirable flowability if 10% (by weight) sand is replaced.

Compared to the reference, the compressive strength, flexural strength, static modulus of elasticity, and dynamic modulus of elasticity of mortar with ground wood chips decreases significantly. This is due to the weak bonding between ground wood chips and mortar. The SEM study shows that the interfaces between matrix and chips are loose and even some cracks exist on the interfaces, which will deteriorate strength and modulus. However, mortar with ground wood chips has at least comparable or higher flexural toughness and toughness index, indicating better energy absorption capacity and post-peak behavior. This is mainly attributed to the ability of arresting cracks of wood chips at micro- and macro- levels and loose interfaces between matrix and wood chips.

In addition, mortar with HTW or LTW has better strength and modulus of elasticity than OW. However, mortar with OW has higher flexural toughness and toughness index than HTW or LTW. The SEM test shows that HTW or LTW has rougher surfaces than OW, which will result in good bonding contributing to strength.

Based on the results in this study, for OW and HTW, the 10% replacement content can lead to a much higher toughness of mortar than 5% replacement content while maintaining the strength at the same level; however, for LTW, 5% replacement content is much better than 10% replacement content. If the volume fraction of aggregates in concrete is assumed as 60-80% and the specific gravity of wood chips is approximately assumed as 1, the 5% and 10% replacement contents by weight of sand can be converted roughly into 2.5-5% and 5-10% by volume of concrete, respectively. Therefore, 5-10% by volume of concrete can be the recommended value for OW and HTW, and 2.5-5% by volume of concrete can be the recommend value for LTW.

CHAPTER 4 IMPACT OF CHEMICAL TREATMENT ON THE PHYSICOCHEMICAL AND MECHANICAL PROPERTIES OF KENAF FIBERS

4.1 Introduction

From the powders and chips introduced in Chapter 2 and Chapter 3, the next three chapters (Chapter 4, Chapter 5, and Chapter 6) switch to address another form of lignocellulosic biomass that has a large length/diameter ratio, which is lignocellulosic fibers. Lignocellulosic fibers are normally used to reinforce cementitious materials, not replace any constituent. Many kinds of lignocellulosic fibers, such as hemp fiber (Awwad et al. 2012), kenaf fiber (Elsaid et al. 2011), and sisal fiber (de Andrade Silva et al. 2010), have been used as potential alternate reinforcement in cementitious materials. Given the availability of kenaf fibers at the Conn Center for Renewable Energy Research at the University of Louisville, in this study, they are selected. This chapter (Chapter 4) mainly focuses on the characterization of kenaf fibers, and the consequent Chapter 5 and Chapter 6 will focus on their application to improve the shrinkage, crack resistance, and flexural properties of cementitious materials.

When kenaf fibers are incorporated into cementitious materials, the common problems (see Chapter 1) associated with lignocellulosic biomass will appear. In order to better exploit kenaf fibers in cementitious materials, they can be chemically modified prior to the application. Because all the chemical components in cementitious materials are

inorganic substances, to eliminate the interruption of utilized chemicals, some inorganic chemicals are preferably selected to treat kenaf fibers. In this study, alkali (sodium hydroxide) is firstly used. In addition, many researchers tend to adopt two-stage treatment (alkaline treatment followed by another treatment) to modify lignocellulosic fibers to achieve better results (Goriparthi et al. 2012; Joseph et al. 1996; Li et al. 2009; Mohammed et al. 2017; Nayak and Mohanty 2018). Therefore, in this study, in addition to the solely alkaline treatment, the pretreated kenaf fibers with sodium hydroxide are further treated by some oxidizing agents (potassium permanganate, potassium dichromate, hydrogen peroxide, and sodium chlorite).

After the raw and chemically treated kenaf fibers were prepared well, a series of tests (chemical composition analysis, thermogravimetric analysis, fourier transform infrared spectroscopy analysis, moisture sorption measurement, scanning electron microscopy test, X-ray diffraction test, and single fiber tensile test) were conducted to examine the physicochemical and mechanical properties of kenaf fibers. The purpose of this study is to find out the characteristics of raw and chemically treated kenaf fibers, and eventually by comparing different chemical treatments identify better chemical treatments that can be used to improve the shrinkage, crack resistance, and mechanical properties of kenaf fiber reinforced cementitious materials.

4.2 Materials and Methods

4.2.1 Fiber Preparation

4.2.1.1 Acid Hydrolysis

Kenaf stalks were obtained from ECOBRIDGE, LLC., Louisville, KY. The bast fibers from the kenaf stalks were separated using an acid retting process. Acid hydrolysis

by sulfuric acid (H_2SO_4 , 95-98% purity) was adapted for retting of kenaf stalks by using a digester (Manufacturer: M/K systems Inc) (Fonseca et al. 2014). In this process, the utilization content of sulfuric acid is 4% (by weight) of dry kenaf stalks, and the ratio of kenaf stalks to solution is set to be 1:5 (by weight). The procedure of acid hydrolysis includes three steps: firstly, the reaction temperature was increased from room temperature to 140 °C in 50min; then, the reactor was kept at 140 °C for 1h; after which the reactor started to cool down. When the temperature of the reactor was low enough, kenaf stalks were taken out of reactor. After acid hydrolysis, kenaf fibers was easily peeled off kenaf cores by hand. These sulfuric acid hydrolyzed kenaf fibers were washed multiple times until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is referred to as the reference, denoted as RKF.

4.2.1.2 Alkaline Treatment

To further improve the properties of the fibers, these acid hydrolyzed kenaf fibers were treated with alkali. Acid hydrolyzed kenaf fibers were treated by 5% sodium hydroxide solution (NaOH , 97% purity, Sigma-Aldrich Corporation) for 1h at room temperature, with the pH slightly higher than 14 ($[\text{OH}^-]$ concentration: 1.25mol/L). The ratio of kenaf fibers to solution was 1:20 (by weight), which is followed by the following treatments. After treatment, kenaf fibers were washed by distilled water until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is denoted as AKF.

4.2.1.3 Alkaline-Potassium Permanganate Treatment

Alkaline pretreated kenaf fibers were further treated by 0.02 % of potassium permanganate (KMnO_4 , 0.1N, 0.02M, Ricca Chemical Company) for 2min at room temperature, with the pH of 8.98. After treatment, kenaf fibers were washed by distilled

water until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is denoted as APPKF.

4.2.1.4 Alkaline-Potassium Dichromate Treatment

Alkaline pretreated kenaf fibers were further treated by 0.02 % of potassium dichromate ($K_2Cr_2O_7$, $\geq 99\%$ purity, Sigma-Aldrich Corporation) for 2min at room temperature, with the pH of 6.33. After treatment, kenaf fibers were washed by distilled water until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is denoted as APDKF.

4.2.1.5 Alkaline-Hydrogen Peroxide Treatment

Alkaline pretreated kenaf fibers were further treated by 10.8ml of hydrogen peroxide (H_2O_2 , 50% purity, v/v, Sigma-Aldrich Corporation) for 100ml of solution for 2h at 85 °C, with the pH of 6.5. After treatment, kenaf fibers were washed by distilled water until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is denoted as AHPKF.

4.2.1.6 Alkaline-Sodium Chlorite Treatment

Alkaline pretreated kenaf fibers were further treated by sodium chlorite ($NaClO_2$, 77.5%-82.5% purity, VWR Company, sodium chlorite : water=1:25,) for 2h at 70 °C, with the pH of 11.10. After treatment, kenaf fibers were washed by distilled water until neutral and then dried in air for 24h, followed by 105 °C for 4h in oven, which is denoted as ASCKF.

4.2.2 Chemical Composition Analysis

The cellulose, hemicellulose, lignin, and extractives of kenaf fibers were determined by using National Renewable Energy Laboratory (NREL) standard (Sluiter et al. 2008; Sluiter et al. 2005). The test was conducted in two steps.

Firstly, the water and ethanol extractives were analyzed by using Soxhlet method. In this study, 3g kenaf fibers were prepared in Soxhlet apparatus. Firstly, water extraction was conducted for 6 hours, and then ethanol extraction was conducted for 16 hours. The amount of extractives is the sum of water extractives and ethanol extractives.

Then the cellulose, hemicellulose, and lignin were analyzed on the extractives-free kenaf fibers. 300mg extractives-free kenaf fibers were firstly acid hydrolyzed using 3ml 72% sulfuric acid for 1h at the temperature of 30°C. Then dilute the sulfuric acid to a 4% concentration by adding 84ml deionized water, and the samples were kept at the temperature of 121°C for 1h. Upon the completion of acid hydrolysis, the acid insoluble residues were filtered out and reserved for acid-insoluble lignin determination. The produced hydrolysate was analyzed by High Performance Liquid Chromatography (HPLC) test, based on which the cellulose and hemicellulose of kenaf fibers can be determined.

The lignin of kenaf fibers is comprised of acid-insoluble lignin and acid-soluble lignin, and they are determined by using different methods. The acid-soluble lignin was calculated by using the UV-Vis absorbance of hydrolysate at the wavelength of 240 nm that was obtained by using UV-visible spectrophotometer. For the determination of acid-insoluble lignin, the reserved acid insoluble residues were firstly dried in an oven at 105±3 °C and then the dried acid insoluble residues were kept in a muffle furnace at the

temperature of 575 ± 25 °C. The weight difference of the acid insoluble residues at 105 ± 3 °C and 575 ± 25 °C is simply defined as the amount of acid insoluble lignin.

4.2.3 Thermo-gravimetric Analysis

Kenaf fibers were ground into fine particles, and thermo-gravimetric analysis (TGA) was conducted to measure the weight loss of kenaf fibers when temperature varies. The test was performed under nitrogen atmosphere with a flow rate of 40ml/min from 25 °C to 600 °C at a heating rate of 10 °C/min. Around 10mg of fibers was used for each run. The purpose was to study how much hemicellulose, lignin, and cellulose are decomposed with the temperature.

4.2.4 Fourier Transform Infrared Spectroscopy Analysis

Kenaf fibers were ground into fine particles for Fourier transform infrared spectroscopy (FTIR) analysis. The FTIR test was conducted by using Spectrum 100 series spectrometer. The spectra were recorded in the range of $650\text{--}4000\text{ cm}^{-1}$ with the resolution of 4 cm^{-1} . The purpose of FTIR test was to observe the change of functional groups, which will help confirm the removal of hemicellulose, lignin, and other impurities of fibers.

4.2.5 Moisture Sorption Measurement

Around 0.5g of kenaf fibers were dried in an oven at 105°C for 4h, and then the weight of initial dried kenaf fibers was measured and recorded as W_0 . The moisture sorption test was conducted by using Temperature Humidity Chamber produced by Cincinnati Sub-Zero company. Dried kenaf fibers were placed in the humidity chamber with 80% of relative humidity at 25 °C. After a given period, kenaf fibers were taken out of chamber. Then the weight of wet kenaf fibers was measured and recorded as W_t . Finally, the percentage of moisture sorption (M_t) was calculated by using eq. (4.1) (Nayak and Mohanty

2018). This above-mentioned process was repeated until the weight of kenaf fibers reaches to an equilibrium state.

$$M_t = \frac{W_t - W_0}{W_0} \times 100 \quad (4.1)$$

where, W_t is the weight of kenaf fibers after absorbing water; W_0 is the weight of initial dried kenaf fibers; M_t is the percentage of moisture sorption.

4.2.6 Scanning Electron Microscopy Test

Scanning electron microscopy (SEM) test was conducted to examine the surface morphology of kenaf fibers. Secondary electron detector at 5kV was used to observe the change of surface morphology of fibers after treatment. The scanning electron microscope VEGA3 provided by TESCAN was used in this study.

4.2.7 X-ray Diffraction Test

X-ray diffraction (XRD) test was conducted to study the crystallinity of fibers, which is characterized by crystallinity index calculated based on peak intensities. The diffraction intensities of Cu K α radiation were recorded between 10 and 45° (2θ -angle range), and the scanning speed is 0.02 °/s. The generator with a current of 40mA and a voltage of 40mV was used. The crystallinity index (I_c) was determined according to the Segal empirical method by using eq. (4.2) below (Mwaikambo and Ansell 2002). The crystallinity index indicates the order of the crystallites rather than the crystallinity of the crystallites. A high crystallinity index indicates the cellulose crystals are better oriented in kenaf fibers and is likely to result in stiff, strong fibers.

$$I_c = \frac{(I_{(002)} - I_{(am)})}{I_{(002)}} \times 100 \quad (4.2)$$

where $I_{(002)}$ is the counter reading at peak intensity at a 2θ angle close to 22° representing crystalline material in kenaf fibers; $I_{(am)}$ is the counter reading at peak intensity at a 2θ

angle close to 18° representing amorphous material in kenaf fibers; I_c is the crystallinity index.

4.2.8 Single Fiber Tensile Test

Tensile strength of single kenaf fiber was measured according to the ASTM C1557-14. The test specimen was prepared in three steps: (1) a tab for mounting the specimen in the test machine was prepared from a thick sheet of paper; (2) a slot with the length of 25.4mm (equal to the gauge length of the specimen) was cut in the middle of the tab; (3) a single randomly selected kenaf fiber was centered in the slot, with each end taped to the corresponding end of the slot. The dimension of the test specimen was presented in **Fig. 4.1**. Both sides of the tab were cut at the mid-gauge after mounting in the test machine. This test was conducted by using MTI universal testing systems. The cross-head speed was set to 8×10^{-6} m/s (0.48mm/min). Through this test, the maximum force (F) that a single kenaf fiber can bear would be obtained. For each kind of kenaf fibers, a total of 20 specimens were tested, and finally the average maximum force (F_{avg}) will be used as representative value.

Fig. 4.1. Single fiber tensile test specimen

In this study, single kenaf fibers were assumed to have circular cross sections. The diameter (d) of single kenaf fiber was evaluated by scanning electron microscopy (SEM) test. For each single kenaf fiber, three positions (middle point and both ends) were measured, and the actual diameter of single kenaf fiber was represented by the average

value. A total of 20 specimens were used for each kind of kenaf fibers (treated with different solutions), and the average diameter (d_{avg}) was calculated. Eventually, based on the average maximum force (F_{avg}) and diameter (d_{avg}) of each kind of kenaf fibers, the tensile strength can be calculated by using eq. (4.3).

$$f_{kft} = \frac{4F_{avg}}{\pi d_{avg}^2} \quad (4.3)$$

where f_{kft} is the tensile strength of single kenaf fiber; F_{avg} is the average tensile force of single kenaf fiber; d_{avg} is the average diameter of single kenaf fiber.

4.3 Results and Discussions

4.3.1 Chemical Composition

The cellulose, hemicellulose, lignin, and extractives of raw and chemically treated kenaf fibers are shown in the **Table 4.1**. It's shown that compared to RKF, chemical treatment can remove some hemicellulose, lignin, and extractives, and increase the cellulose content. Kabir et al. showed that most of cellulose is crystalline and can be harder to decompose than hemicellulose and lignin (Kabir et al. 2013). It has been reported that cellulose provides mechanical strength to the fibers, and from the viewpoint of chemical composition, the strength of fibers can be increased with the increasing cellulose content (Petroudy 2017). Therefore, the chemically treated kenaf fibers can possibly have higher strength than RKF because of higher cellulose content. Additionally, when plant fibers are applied to concrete, the hemicellulose and lignin have been reported to delay cement hydration (Jo and Chakraborty 2015; Kochova et al. 2017). The removal of hemicellulose and lignin can mitigate the delaying effect, so chemically treated kenaf fibers are expected to exhibit better than RKF for the application in concrete.

Table 4.1 also shows that APPKF and APDKF have the similar chemical composition, and AHPKF and ASCKF have the similar chemical composition. Compared to AKF, APPKF and APDKF have slightly increased cellulose content because of the slight removal of hemicellulose, lignin, and extractives. However, AHPKF and ASCKF have much higher cellulose content than AKF, which is believed to attributed to the removal of much lignin and a little hemicellulose. The reason can be attributed to the fact that hydrogen peroxide and sodium chlorite are bleaching chemicals and they can exert delignification on kenaf fibers (Kabir et al. 2012; Mussatto et al. 2008; Siqueira et al. 2013). Of all chemically treated kenaf fibers, AHPKF has the maximum cellulose content, which is believed to result in the strongest fibers among all samples.

Table 4.1 Chemical composition of raw and chemically treated kenaf fibers

Samples	Cellulose (%)	Hemicellulose (%)	Lignin (%)	Extractives (%)
RKF	56.81	13.59	18.27	7.87
AKF	65.24	10.42	15.93	6.56
APPKF	68.77	8.94	15.18	5.16
APDKF	67.78	10.18	14.64	5.30
AHPKF	79.30	9.69	7.22	5.59
ASCKF	75.92	9.03	8.03	6.95

4.3.2 TGA Analysis

The TGA and DTGA curves of kenaf fibers are shown in **Fig. 4.2**. The decomposition of hemicellulose mainly happened at 220–315 °C (Yang et al. 2007). High weight loss is indicative of high hemicellulose content. Compared to the weight loss of RKF (14.62%), the weight loss (W_L) of AKF, APPKF, APDKF, AHPKF, and ASCKF reduces to 8.42%, 7.25%, 7.29%, 7.87%, and 13.17% respectively, as shown in **Table 4.2**. That indicates much hemicellulose is removed from the original fibers after chemical

treatment. This is evidenced by **Fig. 4.2(b)**, a clear bump disappears for chemically treated fibers compared to RKF. Similar conclusion was obtained by Kabir et al (Kabir et al. 2013). Compared to AKF, the weight loss of APPKF, APDKF, and AHPKF is lower, indicating further chemical treatment results in the removal of more hemicellulose. However, the weight loss of ASCKF is increased compared to that of AKF. This cannot be attributed to the increased hemicellulose content, because the chemical composition analysis of ASCKF indicates that ASCKF have less hemicellulose and more cellulose than AKF. Instead, it could be after the removal of much hemicellulose and lignin that act as a protective layer of fibers, some sodium chlorite crystals lay on the surface of ASCKF and even penetrate into ASCKF, which increase the thermal conductivity of ASCKF and thus reduce its thermal stability.

The cellulose mainly decomposes at 315-400 °C with the maximum weight loss (Yang et al. 2007). The weight loss (W_L) is shown in **Table 4.2**. It is shown that the weight loss of AKF (62.12%), APPKF (65.17%), APDKF (63.13%), and AHPKF (63.10%) is higher than that of RKF (52.68%), which indicates the relative content of cellulose is higher after chemical treatment because of the removal of hemicellulose. Furthermore, compared to solely alkaline treatment, the further chemical treatments by KMnO_4 , $\text{K}_2\text{Cr}_2\text{O}_7$, and H_2O_2 will result in much higher cellulose content in kenaf fibers. However, the weight loss of ASCKF (51.29%) is much reduced compared to that of AKF (62.12%). The chemical composition analysis indicates that the cellulose content of ASCKF is increased significantly. The reduced weight loss of ASCKF at 315-400 °C maybe because some cellulose has decomposed in advance (at 220–315 °C) due to the reduced thermal stability.

The thermal decomposition of lignin occurs over a wider temperature range than cellulose and hemicellulose, which is because various oxygen functional groups in lignin decompose at different temperatures (Correia et al. 2016; Kabir et al. 2013). Yang reported that the decomposition of lignin happened slowly mainly from 160 to 900 °C, but at a very low mass loss rate (Yang et al. 2007). Therefore, in the process of hemicellulose and cellulose decomposition, the decomposition of lignin also occurs.

Generally, compared to raw kenaf fibers, after alkaline treatment, much hemicellulose and lignin can be removed. Also, compared to solely alkaline treatment, alkali-potassium permanganate treatment, alkali-potassium dichromate treatment, and alkali-hydrogen peroxide treatment can further remove some hemicellulose of kenaf fibers, resulting in higher cellulose content. This is consistent with the chemical composition analysis result.

ASCKF	13.17	51.29

4.3.3 FTIR Analysis

The FTIR spectra of raw and chemically treated kenaf fibers is shown in **Fig. 4.3**, by which the change in functional groups can be clearly identified. The peak positions and the possible assignments of functional groups for each sample are shown in **Table 4.3**.

The peak at “a” (between 3600 and 3000 cm^{-1}) represents the O-H stretching vibration and hydrogen bond of hydroxyl groups assigned to intramolecular or intermolecular hydrogen bonding and free OH hydroxyl (Célino et al. 2013). The peak at “b” (between 3000 and 2500 cm^{-1}) represents C-H stretching vibration of methyl and methylene groups in cellulose and hemicellulose (Saha et al. 2010). The peak at “c”

(between 2000 and 1693 cm^{-1}) represents the stretching vibration of carbonyl group ($\text{C}=\text{O}$) indicating the existence of ketones and aldehydes (Gao et al. 2012; Mei et al. 2016). It suggests that this peak is due to carboxylic acid and ester components of hemicellulose (Saha et al. 2010). The peak at “d” (between 1693 and 1607 cm^{-1}) is due to absorbed water in fibers (Ray and Sarkar 2001). The peaks at “e” (between 1607 and 1526 cm^{-1}) and at “f” (between 1526 and 1486 cm^{-1}) are due to $\text{C}=\text{C}$ stretching of aromatic ring of the lignin (Célino et al. 2013; De Rosa et al. 2010; Ray and Sarkar 2001). The peaks at “g” (between 1486 and 1438 cm^{-1}) and at “h” (between 1438 and 1395 cm^{-1}) are attributed to CH_2 bending present in cellulose, hemicellulose, and lignin, etc. (De Rosa et al. 2010; Le Troedec et al. 2008; Ray and Sarkar 2001; Sawpan et al. 2011). The peak at “i” (between 1395 and 1347 cm^{-1}) is attributed to CH bending (De Rosa et al. 2010; Le Troedec et al. 2008). The peak at “j” (between 1347 and 1286 cm^{-1}) is attributed to the bending of $\text{C}-\text{O}$ groups of the aromatic ring in polysaccharides (De Rosa et al. 2010). The peak at “k” (between 1286 and 1184 cm^{-1}) is attributed to the $\text{C}-\text{O}$ stretching vibration of acetyl group in hemicellulose and lignin (De Rosa et al. 2010; Sawpan et al. 2011). The peak at “l” (between 1184 and 1140 cm^{-1}) is attributed to $\text{C}-\text{O}-\text{C}$ asymmetrical stretching in cellulose and hemicellulose (Le Troedec et al. 2008). The strong peak at “m” (between 1140 and 912 cm^{-1}) is attributed to $\text{C}-\text{O}$ stretching vibration which belongs to polysaccharide in cellulose (Liu et al. 2009). The peak at “n” (between 912 and 840 cm^{-1}) is attributed to β -Glucosidic linkage in cellulose (Célino et al. 2013). The peak at “o” (between 840 and 650 cm^{-1}) is attributed to $\text{C}-\text{OH}$ out-of-plane bending in cellulose (Le Troedec et al. 2008).

Fig. 4.3 shows that compared to RKF, the peaks at “c” and “k” for AKF disappear, which is mostly due to the removal of hemicellulose after alkaline treatment. This is

consistent with the result obtained by Senthamaraikannan and Kathiresan (Senthamaraikannan and Kathiresan 2018). Furthermore, the chemical composition analysis and TGA result in this study confirm the removal of hemicellulose and lignin. Because much hemicellulose can be removed by sodium hydroxide, these two peaks at “c” and “k” are also absent for APPKF, APDKF, AHPKF, and ASCKF. By making a comparison between the FTIR spectra of AKF, APPKF, APDKF, AHPKF, and ASCKF, no significant differences are observed except for the change of peak intensity. This indicates that after alkaline pretreatment, the further treatment of potassium permanganate, potassium dichromate, hydrogen peroxide, and sodium chlorite does not introduce or remove any functional groups of kenaf fibers.

4.3.4 Moisture Sorption Analysis

Moisture sorption kinetics of raw and chemically treated kenaf fibers is shown in **Fig. 4.4**. The weight of kenaf fibers increases with the time up to 480 min when a relative equilibrium state is reached. The weights of kenaf fibers were recorded at 10, 30, 60, 240, and 480 min after being immersed in the humidity chamber. It is shown that after chemical treatments, the moisture sorption capacity of kenaf fibers decreases, which may be mainly attributed to the chemical and physical changes linked to the removal of cementing materials (Alix et al. 2009). It has been suggested that the hydrophilic nature of plant fibers is mainly attributed to the presence of hemicellulose and cellulose (Correia et al. 2016). Moreover, compared to cellulose, hemicellulose is more hydrophilic and has more capacity to absorb water (Berry and Roderick 2005; Zhang et al. 2011). The removal of hemicellulose and other extractives may lead to the reduced moisture sorption. Pejic et al. also reported that the removal of lignin decreased the moisture sorption of sodium chlorite modified hemp fibers by removing the easily accessible non-cellulosic moisture-absorbing materials (Pejic et al. 2008). In this study, the removal of much hemicellulose, lignin, and extractives after chemical treatment has been confirmed by chemical composition analysis, TGA, and FTIR test, which is believed to be the reason for reducing moisture sorption capacity. The further chemical treatments after alkaline pretreatment seem to reduce the moisture sorption capacity more compared to solely alkaline treatment, with alkaline-hydrogen peroxide treatment and alkaline-sodium chlorite treatment reducing the most.

Fig. 4.4. Moisture sorption kinetics of raw and chemically treated kenaf fibers

4.3.5 SEM Analysis

The surface morphology of raw and chemically treated kenaf fibers is shown in **Fig. 4.5**. From **Fig. 4.5(a)**, the raw kenaf fibers (RKF) show smooth and compact surface morphology. It has been reported that the removal of lignin by alkaline treatment is difficult, because lignin has a strong chain of C–C bonds and aromatic groups (Lazic et al. 2017). Reddy et al also indicated that hemicellulose is much more sensitive to the action of sodium hydroxide at room temperature than lignin or cellulose (Reddy et al. 2013). Therefore, the removal of hemicellulose is expected to change the surface morphology of kenaf fibers. But from the SEM test, it can be seen that the surface of alkaline treated kenaf fibers (AKF) only seems to be a little bit rougher, not obvious, as shown in **Fig. 4.5(b)**. Moreover, compared to **Fig. 4.5(b)**, even if KMnO_4 , $\text{K}_2\text{Cr}_2\text{O}_7$, H_2O_2 , and NaClO_2 can further remove the hemicellulose, lignin and extractives after alkaline treatment, they seem not to result in much rougher surface of kenaf fibers.

Fig. 4.5. Surface morphology of (a) RKF; (b) AKF; (c) APPKF; (d) APDKF; (e) AHPKF; (f) ASCKF

4.3.6 XRD Analysis

The XRD curves of raw and chemically treated kenaf fibers are shown in **Fig. 4.6**. An intense peak at around $2\theta=22^\circ$ for all samples are observed, which corresponds to the crystallinity region of cellulose in kenaf fibers. The intensity of crystalline peak of

chemically treated kenaf fibers is higher than that of untreated fibers, which indicates a higher degree of crystallinity in the treated fiber as indicated by Razak et al (Razak et al. 2014). A valley is observed at around $2\theta=18^\circ$, which is indicative of amorphous region of cellulose in kenaf fibers.

The crystallinity index is calculated based on Eq. (4.2), and the result is shown in **Table 4.4**. The crystallinity index characterizes the order of the crystallite packing rather than the intrinsic crystallinity (Mwaikambo and Ansell 2002), and it is useful only on a comparison basis (Beckermann and Pickering 2008). A high crystallinity index is likely to yield stiff, strong fibers. As compared to RKF, the crystallinity index of AKF, APPKF, APDKF, AHPKF, and ASCKF is increased significantly. Similar conclusions were also obtained by many researchers (Le Troedec et al. 2008; Razak et al. 2014; Reddy et al. 2013; Senthamaraikannan and Kathiresan 2018). This is mainly because some hemicellulose, lignin and other impurities are removed after chemical treatment, leading to better packing of cellulose chains. Sinha and Rout indicated that the removal of hemicellulose (normally separating the cellulose chains) will lead to the formation of new hydrogen bonds between certain of the cellulose chains (Sinha and Rout 2009). After chemical treatment, the crystalline regions of cellulose will be rearranged, which leads to a more crystalline nature of fibers (Reddy et al. 2013).

As compared to AKF, the crystallinity index of APDKF, AHPKF, and ASCKF increases. This may be attributed to the fact that after alkaline treatment, the surface of kenaf fibers becomes more reactive for potassium dichromate treatment, hydrogen peroxide treatment, and sodium chlorite treatment, which will lead to the further removal of non-cellulosic substances. On the contrary, the crystallinity index of APPKF is lower

than that of AKF. This may be because the use of potassium permanganate increases the amorphous cellulose of kenaf fibers. Sawpan et al indicated that the reaction between chemical reagents with cellulose takes place mainly in the amorphous cellulose regions or at the edges of crystalline cellulose regions; the chemical reagents will open the hydrogen-bonded cellulose chains by reacting with the chain ends on the surface of crystallites, as they cannot diffuse into crystalline region, which will make cellulose transfer from crystalline to amorphous state; eventually, the reagents will diffuse into this newly produced amorphous cellulose, reacting with the crystalline cellulose and simultaneously generating more amorphous cellulose (Sawpan et al. 2011).

Hydrogen peroxide and sodium chlorite are two kinds of bleaching agents and can be used to remove the lignin of plant fibers. Compared to other treatments, hydrogen peroxide and sodium chlorite treatments can increase the relative content of cellulosic substances by removing much lignin. In this study, the crystallinity indices of AHPKF and ASCKF are higher than other samples. Overall, of all treatments, alkali-hydrogen peroxide treatment exhibits the best in improving the crystallinity index of kenaf fibers.

Fig. 4.6. XRD curves of raw and chemically treated kenaf fibers

Table 4.4 Crystallinity index of raw and chemically treated kenaf fibers

Sample	Crystallinity index (I_c)
RKF	48.85
AKF	59.54
APPKF	55.67
APDKF	60.50
AHPKF	61.96
ASCKF	60.79

4.3.7 Single Fiber Tensile Test

The average diameter of raw and chemically treated kenaf fibers is shown in **Table 4.5**. Because the removal of hemicellulose, lignin, and other impurities, the diameter of chemically treated kenaf fibers is reduced, which indicates that kenaf fibers become much finer after chemical treatment. The diameter reduction after chemical treatment was also reported by Saha et al (Saha et al. 2010). From **Table 4.5**, it is also shown that alkaline treatment, alkaline-potassium treatment, and alkaline-potassium dichromate do not reduce the diameter significantly; however, for alkaline-hydrogen peroxide treatment and alkaline-sodium chlorite treatment, the diameter is reduced more than the other treatments because of the removal of more lignin. Therefore, of all chemical treatments, alkaline-hydrogen peroxide and alkaline-sodium chlorite treatments can result in the finest fibers.

The strength of raw kenaf fiber (RKF) is 423.01Mpa, which is consistent with the result summarized by Mahjoub et al (Mahjoub et al. 2014). In this study, after alkaline treatment, the tensile strength of kenaf fibers is slightly improved. Similar conclusions are obtained by Senthamaraikannan and Kathiresan who reported that 5% NaOH treatment slightly improved the tensile strength of fibers (Senthamaraikannan and Kathiresan 2018). This intrinsic reason may be the increased cellulose content and also the increased crystallinity index as a result of the removal of hemicellulose, lignin, and extractives. From

Table 4.5, it is also concluded that after alkaline pretreatment, the further chemical treatment by other chemicals can improve the tensile strength more. The alkaline-potassium dichromate treatment, alkaline-potassium permanganate treatment, and alkaline-sodium chlorite treatment only improve the tensile strength slightly. Alkaline-hydrogen peroxide treatment improves the tensile strength more significantly.

Table 4.5 Tensile strength of raw and chemically treated single kenaf fibers

Sample	Diameter (μm)*	Tensile force (N)*	Tensile strength (Mpa)*
RKF	83.24 $\pm$ 13.47	2.30 $\pm$ 0.70	423.01 $\pm$ 117.56
AKF	79.67 $\pm$ 12.85	2.16 $\pm$ 0.77	433.43 $\pm$ 143.19
APPKF	75.30 $\pm$ 11.44	1.89 $\pm$ 0.47	425.00 $\pm$ 95.74
APDKF	77.90 $\pm$ 18.72	2.06 $\pm$ 0.61	432.50 $\pm$ 103.03
AHPKF	62.99 $\pm$ 11.26	1.57 $\pm$ 0.43	503.02 $\pm$ 121.89
ASCKF	65.58 $\pm$ 10.18	1.51 $\pm$ 0.37	447.28 $\pm$ 98.77

* average value $\pm$ standard deviation

4.4 Conclusions

In this study, kenaf fibers were treated by several inorganic chemicals (sodium hydroxide, potassium permanganate, potassium dichromate, hydrogen peroxide, and sodium chlorite) to remove some hemicellulose, lignin, and extractives. After chemical treatment, some hemicellulose, lignin, and extractives of kenaf fibers can be removed, as evidenced by chemical composition analysis, TGA, and FTIR test. Moreover, the reduction in moisture sorption and the improvement in crystallinity index and tensile strength are observed. However, the roughness of surface morphology seems not to be improved significantly after chemical treatment. These chemically treated kenaf fibers are expected to have more potential to improve the crack resistance, durability, and mechanical properties of kenaf fiber reinforced concrete.

Compared to raw kenaf fibers, solely alkaline treatment can always lead to a relatively good result because of the removal of hemicellulose, lignin, and extractives, and

also the increased crystallinity index. Compared to solely alkaline treatment, alkaline-potassium permanganate and alkaline-dichromate treatments have the similarly slight improvement in these properties of kenaf fibers; however, alkaline-hydrogen peroxide and alkaline-sodium chlorite treatments can lead to similarly significant improvement in these properties of kenaf fibers, with alkaline-hydrogen peroxide treatment exhibiting the best.

Even if solely alkaline treatment is not the best way to improve the properties of kenaf fibers, it seems to be a feasible choice from the point of economy. Compared to solely alkaline treatment, if much more improvement in the properties of kenaf fibers is required, the alkaline-hydrogen peroxide treatment can be a good choice.

CHAPTER 5 IMPACT OF MODIFIED KENAF FIBERS ON SHRINKAGE AND CRACKING OF CEMENT PASTES

5.1 Introduction

Based on the study in Chapter 4, the process steps and conditions for chemical treatments were found to have great influences on kenaf fiber properties. Compared to raw kenaf fibers, chemical treatments can remove hemicellulose, lignin, and extractives, and also increase crystallinity index, tensile strength, and surface roughness of kenaf fibers, with alkaline-hydrogen peroxide treatment generally exhibiting the best. Besides, solely alkaline treatment can always lead to a relatively good result although it is not the best way to improve the properties of kenaf fibers, which seems to be a feasible choice from the point of economy. Therefore, raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) are preferably selected to be used in cementitious materials for study.

One main advantage of using kenaf fibers in cementitious materials is to control shrinkage and the corresponding cracking. Autogenous shrinkage and drying shrinkage are two important shrinkages of cementitious materials. Autogenous shrinkage is generally defined as the unrestrained bulk deformation of sealed cementitious materials under a constant temperature, without moisture or mass loss (Gao et al. 2014). Similar to autogenous shrinkage, drying shrinkage also occurs due to the loss of water; however, the

difference lies in that drying shrinkage is mainly caused by external water evaporation (Khairallah 2009). If the autogenous shrinkage and drying shrinkage are restrained by adjunct materials or connected members, some tensile stresses will be developed in cementitious materials (Zhang et al. 2012). When the tensile stress exceeds the tensile strength, the cementitious materials will crack. In this study, the three types of kenaf fibers (RKF, AKF, and AHPKF) with the dosages of 0.25% and 0.5% (by weight of cement), respectively, were used to control shrinkage and cracking of cement pastes. Setting time, autogenous shrinkage test, drying shrinkage cracking test, and scanning electron microscopy analysis were conducted on cement pastes with and without kenaf fibers. The purpose of this study is to identify the effects of fiber type and fiber dosage on the autogenous shrinkage and drying shrinkage cracking of cement pastes.

5.2 Materials and Experiments

5.2.1 Kenaf Fiber Preparation

Kenaf stalks, as shown in Fig. 5.1(a), were obtained from ECOBRIDGE, LLC., Louisville, KY. They were chemically treated and characterized using the procedure introduced in Chapter 4. Based on that study, RKF (**Fig. 5.1(b)**), AKF (**Fig. 5.1(c)**), and AHPKF (**Fig. 5.1(d)**) were selected to be used in cementitious materials for study.

Fig. 5.1. Kenaf: (a) Stalk; (b) RKF; (c) AKF; (d) AHPKF

5.2.2 Fiber Processing

Before applying to cementitious materials, some extra work needs to be done with kenaf fibers to assure good dispersion in cementitious composites. In this study, all dry kenaf fibers were firstly cut into 10 mm in length. Then each 1 gram of dry kenaf fibers were processed for 3s by using 200W electric grinder from the brand of Kingtop. The agglomerated kenaf fibers were separated by the strong external rotating force. Kenaf fibers before and after processing are shown in **Fig. 5.2**.

Fig. 5.2. Kenaf fibers before and after processing: (a) RKF; (b) AKF; (c) AHPKF

5.2.3 Physicochemical and Mechanical Properties of Kenaf Fibers

The physicochemical and mechanical properties of RKF, AKF, and AHPKF were studied in the previous study (Guo et al. 2019). The chemical composition, diameter, single fiber tensile strength, crystallinity index, and moisture sorption (under 80% relative humidity at 25 °C) of these fibers are shown in **Table 5.1**. The results show that RKF has the largest amount of hemicellulose, lignin, and extractives, the highest fiber diameter and moisture sorption, and the lowest cellulose content, crystallinity index, and tensile strength, which is followed by AKF and then AHPKF. In this study, given the low dosages of the fibers (only 0.25% and 0.5% by weight of cement), the water absorption of the fibers has a very minor impact on the w/c ratio and thus is not considered. The surface morphology of these fibers is shown in **Fig. 5.3**. It is shown that compared to RKF, AKF and AHPKF have the similar slightly rougher surface.

Table 5.1 Physicochemical and mechanical properties of kenaf fibers

Samples	Chemical composition				Diameter (μm)*	Tensile strength (Mpa)*	Crystallin ity index (%)	Moisture sorption (%)
	Cellulose (%)	Hemicellulose (%)	Lignin (%)	Extractives (%)				
RKF	56.81	13.59	18.27	7.87	83.24 $\pm$ 13.47	423.01 $\pm$ 117.56	48.85	13.42
AKF	65.24	10.42	15.93	6.56	79.67 $\pm$ 12.85	433.43 $\pm$ 143.19	59.54	13.39

5.2.4 Sample Preparation

Cement pastes were prepared by mixing kenaf fibers, type I/II Portland cement, and tap water. The chemical composition and the mineral clinker compounds of cement are shown in Table 2.2 and

Table 2.3 (Shang and Sun 2019). The w/c ratio was chosen as 0.5 in this study based on the ASTM C109. The fiber dosages were 0.25% and 0.5% by weight of cement. The mix proportions of cement pastes are listed in **Table 5.2**.

Two different mixing procedures were used based on the presence of kenaf fibers. For plain cement paste (without kenaf fibers), cement and water were mixed for 3 minutes. The mixture was then left alone for 2 minutes and then continued to mix for another 3 minutes. For cement paste with kenaf fibers, firstly, kenaf fibers were gradually added to cement for a dry mix for 2 minutes. And then water was introduced to the dry mix that followed the procedures used for plain cement paste.

Table 5.2 Mix proportion of cement pastes

Sample	Water	Cement (Type I/II)	kenaf fiber	Specification
Control	0.5	1	0	Cement paste with no kenaf fibers
RKF0.25	0.5	1	0.0025	Cement paste with 0.25% RKF
AKF0.25	0.5	1	0.0025	Cement paste with 0.25% AKF

AHPKF0.25	0.5	1	0.0025	Cement paste with 0.25% AHPKF
RKF0.5	0.5	1	0.005	Cement paste with 0.5% RKF
AKF0.5	0.5	1	0.005	Cement paste with 0.5% AKF
AHPKF0.5	0.5	1	0.005	Cement paste with 0.5% AHPKF

5.2.5 Setting Test on Cement Pastes

Setting of cement paste is a percolation process in which isolated or weakly bound particles are connected together by the formation of hydration products (Bentz 2008). Setting test was conducted on cement pastes by Vicat test, as specified in ASTM C191 (ASTM 2008). The initial setting time and the final setting time were recorded. For each sample, this test was repeated three times and the average value was adopted.

5.2.6 Autogenous Shrinkage Test on Cement Pastes

Autogenous shrinkage test was conducted based on the corrugated tube protocol by using Auto-Shrink system from Germann Instruments (GI) corporation, as shown in Fig. 5.4. The measurement procedure has been specified by ASTM C1698 (ASTM 2014) and also adopted by many researchers (Kawashima and Shah 2011; Liu et al. 2017). During the test, the fresh cement paste was firstly cast into the corrugated tubes and then vibrated on a vibration table to get rid of air inside as much as possible. Moisture loss can be avoided by encapsulating the paste. The stiffness of the corrugated tube in the radial direction is higher than that in the longitudinal direction, so its volumetric deformation can be transformed into linear deformation when cement paste is at a plastic state (Sant et al. 2011). A digital dilatometer was used to measure the linear autogenous deformation and the data was recorded every 10 min automatically starting approximately 30min after water addition till 7 days. The room temperature was kept at 25 ± 2 °C and the relative humidity was 30 ± 5 %.

Fig. 5.4. Dilatometer with corrugated mould for linear autogenous strain measurement

The measurement was zeroed to the final setting time, based on which the corresponding autogenous strain can be determined using Eqs. (5.1) and (5.2) (ASTM 2014). In this study, the measured autogenous strain curves for all samples ($w/c=0.5$) have the similar shapes. **Fig. 5.5** gives an example of autogenous strain curve measured for RKF0.25. It is shown that during the 7 days of testing, the autogenous strain firstly increases until the maximum value is reached, after which it gradually decreases. However, the measured autogenous strain still remains within the positive region. It should be noted that cement is a multi-phase material. Its hydration is a sophisticated process. Due to the different hydration rates of each clinker phase, volume expansion and shrinkage occurs simultaneously. For example, the quick hydration of C_3A contributes greatly to the volume expansion, but with the progress of hydration, the shrinkage caused by the hydration of C_3S and C_2S gradually take over, so that the volume starts to reduce (e.g. autogenous strain starts to decrease after the peak value). The maximum autogenous strain is a good indication of the material's capacity to overcome shrinkage. Once this peak point is reached, the sample starts to exhibit a shrinkage trend. Shrinkage percentage (SP) is defined based on the maximum autogenous strain using Eq. (5.3) to measure how much the accumulated expansion can be lost after a period of time. A higher SP indicates that the accumulated expansion at early stage is released quickly at later stage. Since the accumulated expansion is beneficial to compensate the shrinkage in the long run, the quick releasing of the

accumulated expansion represents a high risk of severe autogenous shrinkage in the long run.

$$L(t) = L_{\text{ref}} + R(t) - 2 \cdot L_{\text{plug}} \quad (5.1)$$

$$\varepsilon = \frac{L(t) - L(t_{\text{fs}})}{L(t)} \cdot 10^6 \quad (5.2)$$

where $L(t)$ is the length of sample at time t , mm; L_{ref} is the length of reference bar (425 ± 0.5 mm); $R(t)$ is the reading of length gauge with specimen in the dilatometer, mm; L_{plug} is the average length of end plugs, mm; t_{fs} is the final setting time, min; $L(t_{\text{fs}})$ is the length of sample at final setting time, mm; ε is the autogenous strain, $\mu\text{m}/\text{m}$.

$$SP = \frac{\varepsilon_t - \varepsilon_{\text{max}}}{\varepsilon_{\text{max}}} \cdot 100\% \quad (5.3)$$

where ε_t is the autogenous strain at time t ; ε_{max} is the maximum autogenous strain; SP is the shrinkage percentage.

Fig. 5.5. Autogenous strain curve for RKF0.25 (t_{fs} : the final setting time; t_{max} : the time corresponding to the maximum autogenous strain)

5.2.7 Drying Shrinkage Cracking Test on Cement Pastes

Being different from autogenous shrinkage, drying shrinkage is caused by external water evaporation. The cracking on the specimens are caused by the restrains from the steel

plate when the volume of the paste sample starts to change. The drying shrinkage cracking is considered as one of the most important factors that affect the durability of concrete in the long run. The drying shrinkage cracking test was conducted using the procedure shown below. Firstly, $1 \times 0.5 \times 11.25$ in (Width $\times$ Height $\times$ Length) paste beams were cast, as shown in **Fig. 5.6(a)**. After 20 min from cement contacted with water, the cast samples were placed in the oven (taken as the time of zero). From then, the samples were checked every 15 min until the first crack appeared on the sample surface, and it was recorded as the initial cracking time. After 2h, samples were demolded in order to accelerate the water evaporation to promote cracking, as shown in **Fig. 5.6(b)**. The length, width, and depth of each crack on samples were measured using a crack width comparator every 6h in the first 12h and then every 12h until 72h. It should be noted that 5 width values were recorded along the length of each crack, and the average width was adopted for each crack. Meanwhile, the cracking patterns of all samples were captured using a digital camera and then processed using Matlab Software.

Fig. 5.6. Sample (a) casting and (b) demolding

Based on the measurement, for each specimen, the initial cracking time (T_{ic}) was determined when the specimen firstly cracks; the number of cracks (N_c) was recorded with testing time; the total cracking length (L_c) was obtained by summing up the length of each crack; the maximum cracking width (W_{mc}) and the maximum cracking depth (D_{mc}) were recorded using the maximum values of width and depth, respectively, of all cracks on each

specimen. The total cracking area (A_c) of each specimen is calculated as follows. Firstly, for each crack on a specimen, the crack was divided into five parts along its direction, and five width values and corresponding lengths were recorded. The cracking area of each part was obtained by multiplying its width with length, and then the cracking areas of these five parts were summed up to obtain the cracking area of each crack on a specimen. Lastly, the cracking areas of all cracks on a specimen were summed up to obtain the total cracking area on a specimen. Since the drying shrinkage cracking test was repeated three times for each mix proportion, for all parameters used in this study, the average values of three specimens were finally adopted.

5.2.8 Scanning Electron Microscopy Analysis

Scanning electron microscopy (SEM) analysis was conducted on the cement pastes with and without kenaf fibers using NOVA NANOSEM 600™ provided by FEI. The specimens with the thickness of 5mm were prepared. They were firstly polished by using sandpaper and then cleaned by using ultrasonic bath. Before testing, in order to suppress charging effect, gold sputtering was applied to the surface of the specimen. During testing, the Everhart Thornley detector (ETD) in the secondary electron mode was adopted. The beam current and voltage were 80pA and 10kV, respectively.

5.3 Results and Discussions

5.3.1 Setting Time

For all samples, the initial setting time (t_{is}) and the final setting time (t_{fs}) are listed in **Table 5.3**. It is shown that in general, the addition of kenaf fibers to cement pastes can lead to slightly increase of the setting time, which indicates that kenaf fibers can delay the setting of cement pastes a little. Several researchers have reported that the delaying effect

is mainly caused by the hemicellulose, lignin, and extractives of plant fibers (Bilba et al. 2003; Jo and Chakraborty 2015; Vaickelionis and Vaickelioniene 2006). These organic components can delay cement hydration by forming a protective layer around the partially hydrated cement grains or forming a chelate complex with the cations present in the hydrated cement (Jo and Chakraborty 2015). In addition, it was also reported that hemicellulose and lignin are soluble in the alkali solution (John and Anandjiwala 2008; John and Thomas 2008). They can be decomposed into numerous sugars and carboxylic acids when subjected to the alkaline environment of concrete, which can further delay cement hydration (Bilba et al. 2003; Jongvisuttisun and Kurtis 2015; Vaickelionis and Vaickelioniene 2006; Wei and Meyer 2014; Xie et al. 2016).

Of all three types of kenaf fibers, regardless of 0.25% or 0.5% fiber dosage, cement pastes with RKF have the longest setting time, which indicates that RKF delays cement hydration the most. This is because RKF has the largest amount of hemicellulose, lignin, and extractives, as shown in **Table 5.1**. However, by comparing AKF with AHPKF, although AHPKF has less hemicellulose, lignin, and extractives than AKF, AHPKF lead to similar or slightly increased setting time. The reason can be of all three types of kenaf fibers, AHPKF has the least fiber diameter (see **Table 5.1**), which indicates the largest surface area to contact with cement pastes so that extractives etc. are easily released to delay cement hydration.

Table 5.3 Comparison of initial setting time (t_{is}) and final setting time (t_{fs}) of all samples

Samples	t_{is} (h)*	t_{fs} (h)*
Control	5.14±0.32	7.08±0.38
RKF0.25	5.78±0.59	8.13±0.60
AKF0.25	5.14±0.23	7.35±0.45

5.3.2 Autogenous Shrinkage Test

5.3.2.1 Autogenous Length Change

In this study, autogenous length change curves of all samples ($w/c=0.5$) are similar, and take AHPKF0.25 for example, as shown in **Fig. 5.7**. The curve can be divided into five stages by four critical times (t_1 , t_2 , t_3 , and t_4). In stage I ($0\sim t_1$), the length of samples decreases significantly; in stage II ($t_1\sim t_2$), the length of samples stops decreasing and remains unchanged; in stage III ($t_2\sim t_3$), the length of samples increases; in stage IV ($t_3\sim t_4$), the length of samples remains unchanged again; and in stage V (after t_4), the length of samples decreases continuously.

In order to find out the physical meanings of each stage, the four times t_1 , t_2 , t_3 , and t_4 of all samples are summarized in **Table 5.4** and then compared with the initial setting time and final setting time listed in Table 5.3. It is shown that the stage II ($t_1\sim t_2$) is in the vicinity of the initial setting, and in stage III ($t_2\sim t_3$), the final setting is reached. Therefore, in the stage I, the samples have not started initial setting yet and are still in the fluid state. The volume decrease in this stage may result from the dissolution and dissipation of cement particles or some intermediate reactions rather than the hydration of C_3S or C_3A during the dormant period of cement hydration (Bullard et al. 2011; Yang et al. 2017). Since the rigid skeleton has not been developed during the setting period, the shrinkage does not result in tensile stress and is of little significance in early-stage cracking. Around the stage II, the initial setting gradually starts, and more hydration products begin to form. A balance between shrinkage and expansion is reached in this stage. In the stage III, the driving force

of expansion apparently exceeds that of shrinkage. The expansion phenomenon has been observed for cementitious materials with high w/c ratio by many other researchers (Baroghel-Bouny and Kheirbek 2000; Baroghel-Bouny et al. 2006; Van Bunderen et al. 2019). Baroghel-Bouny et al. reported that the expansion is probably related to the amount and the size of various hydration products (Ca(OH)_2 , inner C-S-H, AFt, etc) (Baroghel-Bouny et al. 2006). The crystal growth of hydration products can generate a crystallization pressure on the pore wall, which can result in the expansion of the microstructure (Van Bunderen et al. 2019). Another possible mechanism for the expansion can be the re-absorption of external or internal bleeding water (Marušić and Štirmer 2016; Mohr and Hood 2010; Şahmaran et al. 2009). In the stage IV, the final setting has passed for a long time. With cement hydration progresses, the crystal growth gradually slows down and the water re-absorption is gradually completed, so that the driving force of expansion is reduced. Meanwhile, the chemical shrinkage can create some pores in gradually hardened cement pastes to reduce the internal relative humidity, a process known as self-desiccation (Bentz 2008). The self-desiccation can lead to the autogenous shrinkage that balances the expansion. Therefore, the external expansion phenomenon ceases, and a balance between shrinkage and expansion is reached again in this stage. In the stage V, the hydration gradually reaches a steady state, and the formation of hydration products becomes very slowly, so that the driving force of expansion is very small. The self-desiccation gradually exceeds the expansion and is mainly responsible for the shrinkage.

Fig. 5.7. Autogenous length change curve for AHPKF0.25

Table 5.4 The t_1 , t_2 , t_3 , and t_4 of all samples

Samples	t_1 (h)	t_2 (h)	t_3 (h)	t_4 (h)
Control	4.50	4.67	16.67	18.17
RKF0.25	6.00	6.83	29.17	31.67
AKF0.25	4.83	5.67	17.33	17.67
AHPKF0.25	4.50	5.00	15.33	18.83
RKF0.5	4.33	5.17	24.50	28.5
AKF0.5	3.83	4.67	15.17	21.5
AHPKF0.5	4.50	5.17	23.33	23.83

5.3.2.2 Autogenous Strain and Shrinkage Percentage

The autogenous strain is calculated by using Eqs. (5.1) and (5.2), and the obtained autogenous strain curves of all samples are shown in **Fig. 5.8**. It can be seen that after 7 days, the autogenous strain is still positive, which indicates that even though the volume of the specimen starts to reduce after the maximum autogenous strain, the length of the specimen at 7 days is still longer than that at the final setting. However, it is believed that the autogenous strain will reduce to a negative value if the testing is prolonged. Darquennes et al. reported that this expansion stage (when strain is positive) is significant because it can delay the occurrence of autogenous shrinkage (Darquennes et al. 2011). Moreover, a part

of autogenous shrinkage can be compensated by the volume expansion in this stage. As mentioned in section 5.3.2.1, the crystal growth of hydration products (e.g. quick hydration of C_3A) or re-absorption of bleeding water can provide the driving force of expansion, and the self-desiccation can provide the driving force of shrinkage. For the pastes without fibers in this study, when the driving force of expansion is more than the driving force of shrinkage, so the expansion can be seen at early stage. For the pastes with fibers, kenaf fibers firstly absorb water and then release water during self-desiccation, which can mitigate self-desiccation and thus reduce the driving force of shrinkage. Moreover, 0.5% kenaf fibers are more effective in reducing self-desiccation than 0.25% kenaf fibers. This is what we can see from **Fig. 5.8** that 0.5% kenaf fibers can increase the expansion obviously. After the maximum strain is reached, the specimens exhibit a shrinkage trend. One reason is due to the slowed crystal growth of hydration products. Another reason is that with the hydration progresses, the pore structure of cement pastes is denser and the relative humidity is lower, so the self-desiccation is becoming more aggravating. Meanwhile, with more and more water is drained from kenaf fibers, the water supply ability of kenaf fibers to reduce the self-desiccation and thus the driving force of shrinkage is decreasing. Therefore, the influence of kenaf fibers on expansion is even more significant than on shrinkage.

Fig. 5.8 also shows that the autogenous strain curves include ascending and descending parts, which indicates that after final setting, the degree of expansion of cement pastes increases until the maximum autogenous strain is reached. The maximum expansion corresponding to the peaks in **Fig. 5.8** is taken as the reference, after which the specimens exhibit a shrinkage trend (as shown by the descending part of curves). This descending part

of curves is mainly dominated by the self-desiccation and the crystal growth of hydration products. Assuming a linear line is drawn using the two points corresponding to the maximum strain and the strain at 7 days, the slope of the control specimen is $-1.65 \mu\text{m}/(\text{m}\cdot\text{h})$; however, the slope of specimens with 0.25% and 0.5% kenaf fibers varies from -1.33 to $-1.20 \mu\text{m}/(\text{m}\cdot\text{h})$ and from -1.28 to $-1.17 \mu\text{m}/(\text{m}\cdot\text{h})$, respectively. These descending parts of strain curves have similar slopes although a slight difference exists. This can be due to the fact that in this stage, the effect of fibers on the above mentioned two factors (self-desiccation and crystal growth) is not so significant. This may not indicate that the influence of fibers on autogenous shrinkage is almost the same. In this study, different fibers can lead to different autogenous strain values, implying different autogenous shrinkage potentials.

Fig. 5.8. The autogenous strain curves of all samples

Based on **Fig. 5.8**, the maximum autogenous strains ($\epsilon_{\max}$) and shrinkage percentages (SP) of all samples are recorded and listed in **Table 5.5**. It is believed that cement pastes with a larger maximum autogenous strain have more capacity to compensate

the shrinkage in the long run. Moreover, a lower SP is indicative of a lower autogenous shrinkage.

Table 5.5 The maximum autogenous strain ($\epsilon_{\max}$) and shrinkage percentage (SP) of all samples

Samples	$\epsilon_{\max}$ ($\mu\text{m/m}$)	SP (%)
Control	265.75	93.20
RKF0.25	227.90	79.55
AKF0.25	253.32	71.43
AHPKF0.25	258.52	70.99
RKF0.5	287.64	62.16
AKF0.5	327.01	52.91
AHPKF0.5	384.22	43.99

5.3.2.3 The Effect of Fiber Dosage on Autogenous Shrinkage

Table 5.5 shows that compared to the control, 0.25% RKF leads to less $\epsilon_{\max}$ and 0.25% AKF or 0.25% AHPKF leads to similar $\epsilon_{\max}$. The reason can be 0.25% kenaf fibers have the slight delaying effect on cement hydration, as discussed in section 5.3.1, which disturbs the crystal growth of hydration products that is responsible for the expansion. Therefore, the expansion phenomenon of cement pastes with 0.25% kenaf fibers seems to be slightly reduced compared to the control. However, Table 5.5 shows that compared to the control, 0.5% kenaf fibers can increase $\epsilon_{\max}$ significantly. The occurrence of expansion phenomenon is the resultant effect of expansion and shrinkage. 0.5% kenaf fibers have similar delaying effect on cement hydration to 0.25% kenaf fibers (shown in section 5.3.1), which can possibly lead to the similar disturbing effect on crystal growth of hydration products and thus the similar reduced expansion force. However, 0.5% kenaf fibers can provide more fibers to restrain the shrinkage of samples than 0.25% kenaf fibers and thus make the shrinkage less. Therefore, cement pastes with 0.5% kenaf fibers can exhibit much more expansion than those with 0.25% kenaf fibers.

Table 5.5 also shows that compared to the control, regardless of 0.25% or 0.5% kenaf fibers, the SP of all samples is reduced. Moreover, cement pastes with 0.5% kenaf fibers have lower SP than those with 0.25% kenaf fibers. Therefore, it can be concluded that kenaf fibers can mitigate autogenous shrinkage of cement pastes, with 0.5% fiber dosage reducing more than 0.25% fiber dosage. The reason can be more kenaf fibers provide more water for internal curing during self-desiccation that can reduce the capillary tension in the pore solution and thus reduce the autogenous shrinkage (Bentz and Weiss 2011; Jongvisuttisun et al. 2013). The internal curing strategy is effective because the distance that water travels to the surrounding voids is reduced compared to traditional external curing (Kawashima and Shah 2011). In addition, more kenaf fibers can provide the hardened cement pastes with greater shrinkage resistance, resulting in less shrinkage (Saje et al. 2010).

5.3.2.4 The Effect of Fiber Type on Autogenous Shrinkage

Table 5.5 shows that among all three types of kenaf fibers (RKF, AKF, and AHPKF), RKF can lead to the lowest $\varepsilon_{\max}$ and highest SP , indicating RKF reduces the autogenous shrinkage the least. One reason can be RKF has the largest delaying effect on cement hydration, as discussed in section 5.3.1, which can exert the most negative effect on the crystal growth of hydration products and thus the expansion. Another reason may be because of the least internal curing efficiency of RKF. Jongvisuttisun indicated that the internal curing efficiency is more related to the physical morphology than chemical composition of fibers (Jongvisuttisun 2014). The removal of hemicellulose and lignin by alkaline treatment can increase cell wall porosity (Mwaikambo and Ansell 2003; Shi et al. 2018), which can alter the moisture

transportation rate from the lumen and cell wall to the surrounding cement pastes (Jongvisuttisun 2014). The third reason can be that RKF has higher fiber diameter than AKF and AHPKF, as shown in **Table 5.1**. It was reported that at a given fiber volume fraction, coarser fibers can have smaller surface area and less number of fibers to bond with the cementitious matrix (Banthia and Gupta 2006). In addition, the relatively smoother surface texture of RKF (as shown in Fig. 5.3) can lead to the reduced fiber-matrix bonding, which can reduce the pull-out resistance of fibers from the matrix (Toledo Filho et al. 2009). Therefore, RKF is believed to be not as effective as AKF and AHPKF in reducing the autogenous shrinkage of cement pastes.

By comparing AKF and AHPKF, AHPKF can lead to higher $\varepsilon_{\max}$ and lower SP than AKF, indicating better reduction in autogenous shrinkage. Considering AHPKF has the similar or slightly higher delaying effect on cement hydration and also the similar surface texture to AKF, the reason can be AHPKF has much smaller fiber diameters than AKF (see **Table 5.1**), and also possibly higher internal curing efficiency that needs to be further verified.

5.3.3 Drying Shrinkage Cracking Test

5.3.3.1 Cracking Pattern

To check the effect of adding kenaf fibers on the drying shrinkage cracking of cement pastes, the cracking patterns of all samples are firstly examined, as shown in **Fig. 5.9**. Due to the different restraints along the length and width of the beams, transverse parallel cracks are formed on the surface of samples (Chen and Baker 2004). From the figure, it can be seen that compared to the control (**Fig. 5.9(a)**), the addition of kenaf fibers can decrease the number of cracks (N_c) on the surface of samples, and also for some samples with fibers,

some cracks do not extended to the full width of the specimen. This indicates that kenaf fibers can play an important role in controlling shrinkage cracking.

Fig. 5.9. Cracking pattern of (a) Control; (b) RKF0.25; (c) RKF0.5; (d) AKF0.25; (e) AKF0.5; (f) AHPKF0.25; and (g) AHPKF0.5.

5.3.3.2 Cracking Parameters

The initial cracking time (T_{ic}) of all samples is summarized in **Table 5.6**. A longer initial cracking time is indicative of a delayed shrinkage cracking. It should be noted that the T_{ic} of AHPKF0.5 is absent in **Table 5.6** because one of the three AHPKF0.5 samples did not crack during the observing window, so that the average initial cracking time cannot be calculated. This in turn indicates 0.5% of AHPKF fibers are very effective in minimizing cracking in the specimen caused by drying shrinkage. The number of cracks (N_c), the total cracking length (L_c), the total cracking area (A_c), the maximum cracking width (W_{mc}), and the maximum cracking depth (D_{mc}) at 72h of all samples are also listed in **Table 5.6**. It

can be seen that adding fibers, either treated or non-treated, can minimize the crack numbers and reduce crack width, length, areas, and depth effectively.

Table 5.6 The T_{ic} and N_c , L_c , A_c , W_{mc} , and D_{mc} at 72h of all samples

Samples	T_{ic} (h)	N_c	L_c (mm)	A_c (mm ²)	W_{mc} (mm)	D_{mc} (mm)
Control	1.94	3.67	84.83	41.90	0.80	12.00
RKF0.25	2.33	2.33	55.17	8.15	0.32	11.83
AKF0.25	2.17	3.00	63.17	10.84	0.28	11.50
AHPKF0.25	2.42	1.67	38.17	5.73	0.23	11.67
RKF0.5	2.42	2.00	42.00	2.68	0.13	11.50
AKF0.5	2.50	1.67	31.83	1.55	0.07	9.17
AHPKF0.5	-	0.67	15.67	0.97	0.05	8.00

Note: “-” indicates one of the three AHPKF0.5 samples does not crack, and the average initial cracking time cannot be calculated. All values listed in this table are the averages of three samples.

5.3.3.3 The Effect of Fiber Dosage on Drying Shrinkage Cracking

Regardless of the fiber type used, the effect of fiber dosage on drying shrinkage cracking is similar. Using pastes with RKF as examples, and the comparison of the number of cracks (N_c), the total cracking length (L_c), the total cracking area (A_c), the maximum cracking width (W_{mc}), and the maximum cracking depth (D_{mc}) is plotted in **Fig. 5.10**. It shows that the addition of kenaf fibers can not only delay the shrinkage cracking but also reduce the cracking severity significantly. It is noted that in **Fig. 5.10(e)**, all samples have almost equal maximum cracking depths at 72h, which is due to the fact that after 72h of crack propagation, these cracks progressively reach the full depth of the samples. The increased shrinkage cracking resistance by kenaf fibers can be explained in several ways. Firstly, plant-based fibers can reduce tensile stress developed in cementitious materials through reinforcement and internal curing effects and also transfer tensile stress from the matrix to fibers (Jongvisuttisun and Kurtis 2015). Even, after cracking, plant-based fibers

can bridge cracks and prevent them from developing. In addition, Qi et al. stated that some preferential bleeding channels along fibers can be formed, which supply water to replenish the drying surface and reduce the magnitude of capillary stress and thus reduce the shrinkage cracking (Qi et al. 2003).

Fig. 5.10 also shows that 0.5% fiber dosage can decrease N_c , L_c , A_c , W_{mc} , and D_{mc} more than 0.25% fiber dosage, which indicates that 0.5% kenaf fibers exhibit better performance than 0.25% kenaf fibers in controlling shrinkage cracking. Similar conclusions were obtained by some other researchers who suggested that the number of cracks, the total crack area, and the maximum crack width can be reduced with the increase of fiber dosage (Banthia and Gupta 2006; Qi et al. 2003; Soleimani et al. 2013). This can also be seen from the cracking sections as shown in **Fig. 5.11**. For the control, after cracking, the sample is turned into two individual parts. However, for RKF0.25 and RKF0.5, some kenaf fibers are not broken while cracking and they serve as bridges between two cracked sections by increasing the tensile capacity. Moreover, 0.5% kenaf fibers (**Fig. 5.11(c)**) provide more fibers than 0.25% kenaf fibers (**Fig. 5.11(b)**) to bridge cracks and thus control shrinkage cracking.

In order to identify the effect of kenaf fibers on controlling shrinkage cracking from the microscopic point of view, the SEM test was conducted on the control, RKF0.25, and RKF0.5, as shown in **Fig. 5.12**. The cracks on the samples are circled using dashed ellipses. For the control, the individual cracks can connect each other and then develop into major cracks, as shown in **Fig. 5.12(a)**. However, for RKF0.25 and RKF0.5, some cracks stop propagating when they meet with kenaf fibers (see **Fig. 5.12(b)** and **Fig. 5.12(c)**). The

kenaf fibers seem to serve as barriers that can block crack propagation, which can prevent the development of individual cracks into major cracks.

5.3.3.4 The Effect of Fiber Type on Drying Shrinkage Cracking

The effect of fiber type on drying shrinkage cracking is a little complicated and varies based on different fiber dosages. For cement pastes with 0.5% kenaf fibers, the comparisons of the number of cracks (N_c), the total cracking length (L_c), the total cracking

area (A_c), the maximum cracking width (W_{mc}), and the maximum cracking depth (D_{mc}) are shown in **Fig. 5.13**. Among all three fiber types (RKF, AKF, and AHPKF), AHPKF is the most effective in decreasing N_c , L_c , A_c , W_{mc} , and D_{mc} , which is followed by AKF and then RKF. One reason can be that, compared to RKF, the similar rougher surface of AKF and AHPKF (as shown in Fig. 5.3) can improve the shrinkage cracking resistance by improving the bonding between fibers and the matrix (Rahmani et al. 2012; Toledo Filho et al. 2009). Since AHPKF has the smallest diameter, which means the largest surface area and number of fibers among the three. This increases the chance of AHPKF fibers to go cross the given section or bridge the cracks to resist crack initiation and propagation.

(a)

(b)

(c)

(d)

(e)

Fig. 5.13. Comparison of (a) N_c , (b) L_c , (c) A_c , (d) W_{mc} and (e) D_{mc} for cement pastes with 0.5% kenaf fibers

For cement pastes with 0.25% kenaf fibers, the comparisons of the number of cracks (N_c), the total cracking length (L_c), the total cracking area (A_c), the maximum cracking width (W_{mc}), and the maximum cracking depth (D_{mc}) are shown in **Fig. 5.14**. **Fig. 5.14(e)** shows that when 0.25% kenaf fibers are used, the fiber type almost does not have any effects on D_{mc} . Similar to cement pastes with 0.5% kenaf fibers, of all three fiber types, AHPKF is the most effective in decreasing N_c , L_c , A_c , and W_{mc} (shown in **Fig. 5.14(a-d)**), which is indicative of the most shrinkage cracking resistance. However, by comparing RKF0.25 and AKF0.25, AKF0.25 lead to lower T_{ic} (Table 5.6) and higher N_c , L_c , and A_c , but lower W_{mc} . This indicates that AKF0.25 samples seem to crack more easily than RKF0.25 samples; however, AKF0.25 has better control over the crack width than RKF0.25. This can be attributed to the relative rough surface texture of the fibers after alkaline treatment, which in turn enhance the bonding between the fiber and the paste matrix.

Fig. 5.14. Comparison of (a) N_c , (b) L_c , (c) A_c , (d) W_{mc} and (e) D_{mc} for cement pastes with 0.25% kenaf fibers

5.4 Conclusions

The setting, autogenous shrinkage, and drying shrinkage cracking of cement pastes with raw, alkaline treated, and alkaline-hydrogen peroxide treated kenaf fibers were investigated in this study. Some key conclusions are summarized below.

The addition of 0.25% or 0.5% kenaf fibers to cement pastes can have the similarly slight delaying effect on cement hydration in comparison with the control. Of all three types of kenaf fibers (RKF, AKF, and AHPKF), RKF can delay cement hydration the most, because RKF has the most hemicellulose, lignin, and extractives. Although AHPKF has the least hemicellulose, lignin, and extractives, AHPKF seems not to delay cement hydration the least. This is because AHPKF has the least fiber diameter, which indicates that AHPKF has the largest surface area to contact with cement pastes and extractives, etc. can be dissipated in cement pastes to delay cement hydration. Therefore, both fiber diameter and chemical composition of fibers should be considered in studying the effect of plant fibers on cement hydration.

The autogenous shrinkage test indicates that the autogenous strain firstly increases (expansion) until the maximum strain is reached. Samples with kenaf fibers, especially those with 0.5% fibers have significantly higher expansion compared to the control. After the maximum strain, the autogenous strain decreases, indicating a shrinkage trend. Samples with kenaf fibers have a relatively gradual decline, indicating a slower pace of shrinkage

Compared to the control, the application of kenaf fibers (0.25% or 0.5% fiber dosage) to cement pastes can not only reduce the autogenous shrinkage potential as reflected by the increased autogenous strain, namely the increased degree of expansion, but also reduce the drying shrinkage cracking significantly, with 0.5% fiber dosage

exhibiting better performance than 0.25% fiber dosage. The reduction in autogenous shrinkage is mainly because with the increase of fiber dosage, kenaf fibers can absorb more water for internal curing and also provide greater shrinkage resistance. The reduction in drying shrinkage cracking is mainly due to the fact that more kenaf fibers can provide more bleeding channels to replenish the drying surface, serve as more bridges to connect cracks, and block crack propagation. If the volume fraction of aggregates in concrete is assumed as 60-80% and the specific gravity of kenaf fibers is approximately assumed as 1, 0.12-0.24% fiber dosage by volume of concrete (0.5% fiber dosage by weight of cement) can be a recommended value.

Of all three types of kenaf fibers, AHPKF can reduce autogenous shrinkage and drying shrinkage cracking the most. By comparing RKF and AKF, when 0.25% kenaf fibers are used, AKF can reduce autogenous shrinkage more but reduce drying shrinkage cracking less; however, when 0.5% kenaf fibers are used, AKF can reduce both autogenous shrinkage and drying shrinkage cracking more.

Through the study, it can be seen that the shrinkage and cracking of cement pastes can be controlled by kenaf fibers. Given that the chemicals used for fiber treatment are affordable and the amount of fiber usage is low, the slightly increased cost and energy consumption is acceptable. Moreover, the treatment process is still being optimized to further reduce the cost and energy consumption. Therefore, using kenaf fibers to control shrinkage and cracking has the potential to be applied on large scale for infrastructures such as pavements and sidewalks.

CHAPTER 6 EXPERIMENTAL AND FINITE ELEMENT ANALYSIS ON FLEXURAL BEHAVIOR OF MORTAR BEAMS WITH CHEMICALLY MODIFIED KENAF FIBERS

6.1 Introduction

From the study in Chapter 5, the shrinkage and cracking of cementitious materials can be controlled well by kenaf fibers, especially chemically treated kenaf fibers. It is believed that kenaf fibers can be used to improve the flexural behavior of cementitious materials. Many researchers have demonstrated that alkaline treated lignocellulosic fibers can improve the strength and toughness of lignocellulosic fiber reinforced cementitious materials (Andiç-Çakir et al. 2014; Jo et al. 2016; Zhou et al. 2017). Besides, Tong et al. reported that the treated lignocellulosic fibers through the combination of 6% potassium hydroxide (KOH) alkaline solution and 10% hydrogen peroxide (H_2O_2) could effectively increase the cracking resistance more than untreated or solely KOH treated fibers (Tong et al. 2014). Therefore, following Chapter 5, raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) were incorporated into mortars in this study to expect to improve the flexural behavior of the mortars.

In this study, the dosages of RKF, AKF, and AHPKF were 0.25%, 0.5%, and 0.75% by weight of cement. Moreover, 0.2% (by weight of cement) superplasticizer was added

into some of 0.75% fiber reinforced mortars to improve their flowability. Compressive test, flexural test, and scanning electron microscopy analysis were conducted on mortars with RKF, AKF, and AHPKF, respectively. The purpose of this study is to identify the effect of fiber type and fiber dosage and also the effect of superplasticizer on flexural behavior of mortars.

Lastly, finite element analysis (FEA) was carried out using the finite element software MSC MARC to simulate stress and strain distributions in mortar beams under flexure. The smeared cracking model was adopted to study the cracking of specimens, in which the cracking strain rather than cracking opening displacement was defined (Lu et al. 2005). The cracking strain, together with the stress, of specimens was examined in detail. The effect of fiber dosage on the load-bearing capacity and cracking strain of specimens was examined theoretically through FEA, which can provide some guidance for future research.

6.2 Materials and Experiments

6.2.1 Kenaf Fiber Preparation and Processing

Following the Chapter 5, raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) were selected and then processed using the procedure introduced in section 5.2.2 to ensure good dispersion in mortar. And the corresponding physicochemical and mechanical properties of these three types of kenaf fibers are shown in **Table 5.1**.

6.2.2 Specimen Preparation

The materials used in this study include type I/II Portland cement, polycarboxylate-based superplasticizer, kenaf fibers (RKF, AKF, and AHPKF), silica sand, and tap water.

The chemical composition and the mineral clinker compounds of cement are shown in Table 2.2 and

Table 2.3, respectively (Shang and Sun 2019). The superplasticizer is SUPERFLO 2000 RM in accordance with Types A and F both in ASTM C494 and in AASHTO M194. In terms of kenaf fibers, three fiber dosages (0.25%, 0.5%, and 0.75% by weight of cement) are adopted. Moreover, for the fiber dosage of 0.75%, some of specimens are mixed with 0.2% (by weight of cement) superplasticizer to improve flowability. The mix proportion (by weight) of all mortar specimens is listed in **Table 6.1**.

A standard Hobart mixer at the speed level of “1” (136 rpm) was used to prepare mortars (Ramezani et al. 2019). Three different mixing procedures were used based on the presence of kenaf fibers and superplasticizer. For plain mortars (without kenaf fibers and superplasticizer), sand and cement were dry mixed for 2 minutes, and then water was added to mix for 3 minutes. Afterward, the mixture was left rested for 2 minutes and then continued to mix for another 3 minutes. For mortars with kenaf fibers but without superplasticizer, sand and cement were first dry mixed for 2 minutes, during which kenaf fibers were gradually added into the mixture to ensure good dispersion. And then water was introduced to the dry mix that followed the procedures used for plain mortars. For mortars with both kenaf fibers and superplasticizer, the procedure is the same as the second one except for that the superplasticizer was pre-mixed with water.

For each case listed in **Table 6.1**, three 2×2×2 in cubes and four 1×1×11.25 in (width×height×length) beams were cast using stainless steel molds. The specimens were sealed for the first 24 hours and then were demolded. The cubes of each case were selected to estimate the density by dividing the weight of each cube by its volume, and then the

average density of three cubes was adopted. The density of all cases is summarized in **Table 6.2**. Afterward, all specimens including cubes and beams were cured in a moisture room with 100% humidity and 22°C till 28 days.

Table 6.1. Mix proportion (by weight) of mortars

Specimens	Water	Cement	Sand	Kenaf fiber	Superplasticizer	Specification
Control	0.5	1	2.25	0	0	Mortar with no kenaf fibers
RKF0.25	0.5	1	2.25	0.0025	0	Mortar with 0.25% RKF
AKF0.25	0.5	1	2.25	0.0025	0	Mortar with 0.25% AKF
AHPKF0.25	0.5	1	2.25	0.0025	0	Mortar with 0.25% AHPKF
RKF0.5	0.5	1	2.25	0.005	0	Mortar with 0.5% RKF
AKF0.5	0.5	1	2.25	0.005	0	Mortar with 0.5% AKF

*Note: The values are average value±standard deviation.

6.2.3 Compressive Test

A universal testing machine and 2×2×2 in mortar cubes were used for the compressive test, as shown in **Fig. 6.1**. Based on the maximum load (F) obtained from this test, compressive strength is calculated using Eq. (6.1).

Fig. 6.1. Universal testing machine for compressive test

$$\sigma_c = \frac{F}{A} \quad (6.1)$$

where σ_c is compressive strength; F is maximum load; A is cross section area of a cube (2×2 in²).

6.2.4 Flexural Test

A universal testing machine and 1×1×11.25 in mortar beams with the span length of 10 in between two supporters were used for the flexural test, as shown in **Fig. 6.2**. A load cell with the model of LCCA-750 (750 lbf capacity) produced by OMEGATM was used to measure the force that a beam can bear. A Linear Variable Differential Transformer (LVDT) with the model of LD620-2.5 produced by OMEGATM was used to record the deflection at mid-span of the beam. From the flexural test, the load-deflection curve can be obtained directly, and then based on the maximum load, flexural strength is calculated using Eq. (6.2).

Fig. 6.2. Universal testing machine for flexural test

$$\sigma_f = \frac{3Fl}{2bh^2} \quad (6.2)$$

where σ_f is flexural strength; F is maximum load; l is span length of a beam; b is width of a beam; h is height of a beam.

Based on the load-deflection curve from the flexural test, the data between 10% F and 40% F are fitted into a straight line. Then, the slope of the fitted straight line can be obtained, by which the modulus of elasticity is calculated using Eq. (6.3).

$$E = \frac{ml^3}{4bh^3} \quad (6.3)$$

where E is modulus of elasticity; l is span length of a beam; m is slope of the fitted straight line; b is width of a beam; h is height of a beam.

Besides, based on the load-deflection curve from the flexural test, flexural toughness can also be calculated. The flexural toughness is obtained by calculating the area of the load-deflection curve, which is used to evaluate the energy absorption of mortar. In this study, the area of the load-deflection curve up to a net deflection of 1/150 of the span length is defined as the flexural toughness conforming to ASTM C1609 (ASTM 2019).

6.2.5 Scanning Electron Microscopy Analysis

Scanning electron microscopy (SEM) analysis was conducted on the fracture surfaces of mortar beams after the flexural test using VEGA3 provided by TESCAN. The specimens with a thickness of 5 mm were prepared. Before testing, to suppress the charging effect, gold sputtering was applied to the surface of the specimens. During testing, the secondary electron detector at 10 kV was used to observe the fracture surfaces of mortar beams and also examine the area surrounding kenaf fibers.

6.3 Finite Element Analysis

To visually examine the stress and cracking strain within mortar beams under flexure, the finite element analysis was conducted to do simulation. The effect of fiber dosage on the loading bearing capacity and cracking strain was assessed, which may provide some insights and guidance for future study. The FEA processes are elaborated as follows.

6.3.1 Mortar

6.3.1.1 Constitutive Relationship under Compression and Tension

The stress-strain relationship of mortar under compression and tension is shown in **Fig. 6.3**. The formulae for the compressive stress-strain relationship are shown in Eqs. (6.4-6.6) (Safdar et al. 2016; Zhang and Koizumi 2010). The compressive modulus of elasticity of mortar is related to its compressive strength, and it can be initially estimated using Eq. (6.7) given by ACI (2014). In this study, the crushing strain (ε_{cu}) does not have a substantial effect on simulation, and it is defined as 0.005 that is slightly higher than the strain corresponding to peak compressive stress.

$$\sigma_c = \frac{f'_c \alpha \left(\frac{\varepsilon_c}{\varepsilon'_c} \right)}{\alpha - 1 + \left(\frac{\varepsilon_c}{\varepsilon'_c} \right)^\alpha} \quad (6.4)$$

$$\alpha = \left(\frac{f'_c}{\xi}\right)^3 + 1.55 \quad (6.5)$$

$$\varepsilon'_c = \frac{2f'_c}{E_c} \quad (6.6)$$

$$E_c = 4700\sqrt{f'_c} \quad (6.7)$$

where σ_c is compressive stress of mortar (MPa); ε_c is compressive strain of mortar; E_c is compressive modulus of elasticity (GPa); ε'_c is compressive strain at peak compressive stress; f'_c is compressive strength of mortar (MPa). The coefficient of variability ξ increases with increasing compressive strength of mortar. The literature suggests that when $f'_c=42.5$ MPa, $\xi=32.4$ and when $f'_c=88.0$ MPa, $\xi=71.4$. For all other compressive strengths, ξ can be calculated using the linear interpolation method (Zhang and Koizumi 2010). In this study, the tested compressive strength of mortar is 55.16 MPa, therefore, ξ is calculated as 43.3.

In the tensional zone, before cracking the linear elasticity is used, which are defined by the tensile strength (f'_t) and tensile modulus of elasticity (E_t) assumed to be the same as the compressive modulus of elasticity (E_c). However, the tensile strength of mortar is difficult to test, and the value is initially estimated using Eq. (6.8) (Safdar et al. 2016). When the tensile stress reaches the tensile strength of the mortar f'_t , cracking occurs. After cracking, the tensile stress of mortar linearly reduces to zero at the strain ε_{tu} , and the slope of the descending curve is defined as the softening modulus (E_s). In this study, the mortar behavior is considered independent of the reinforcement. For plain mortars, the softening modulus can be defined as a very large value to model the brittle failure behavior.

$$f'_t = 0.23(f'_c)^{2/3} \quad (6.8)$$

where f_t' is tensile strength of mortar (MPa); f_c' is compressive strength of mortar (MPa).

Fig. 6.3. Stress-strain relationship of mortar under (a) compression and (b) tension

6.3.1.2 Yielding Criterion

Mortar under compression is treated as quasi-brittle material, and the yielding function proposed by Buyukozuturk is used, as defined using Eqs. (6.9-6.12), which is already included in MSC.MARC (Buyukozturk 1977; Lu et al. 2005; Safdar et al. 2016; Teng et al. 2013).

$$f = \beta\sqrt{3}\bar{\sigma}I_1 + \gamma I_1^2 + 3J_2 - \bar{\sigma}^2 \quad (6.9)$$

$$I_1 = \sigma_{11} + \sigma_{22} + \sigma_{33} \quad (6.10)$$

$$J_2 = \frac{1}{2}S_{ij}S_{ij}, \quad S_{ij} = \begin{bmatrix} \sigma_{11} - \sigma_m & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} - \sigma_m & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} - \sigma_m \end{bmatrix} \quad (6.11)$$

$$\sigma_m = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \quad (6.12)$$

where I_1 and J_2 are first invariant of stresses and the second invariant of deviatoric stresses, respectively; β and γ are materials constants and equal to $\sqrt{3}$ and 0.2,

respectively; $\bar{\sigma}$ is one third of the yielding stress that is equal to one-third of the uniaxial compressive strength.

6.3.1.3 Cracking

Smeared crack model is adopted to study the cracking behavior of mortar by using the Cracking option in MSC MARC. The smeared crack model does not track individual “macro” cracks but treats a crack as a geometry entity instead (Barth and Wu 2006; Teng et al. 2013). It allows one crack at one integration point for one-dimensional elements, two orthogonal cracks for two-dimensional elements, and three orthogonal cracks for three-dimensional elements. Constitutive calculations are performed independently at each integration point of the FEA model to consider the presence of cracks, and the cracks affect the stress associated with the integration point (Barth and Wu 2006). A crack initiates in a perpendicular direction to the maximum principal stress when the maximum principal stress reaches the tensile strength of the mortar (Al-Jelawy 2013).

To adopt the smeared crack approach, the relative displacement of the crack surface is represented by cracking strain that is defined as the difference between the total strain and the strain (considered to be merely elastic) of the mortar (Rots et al. 1985). The crack band theory relates the crack opening width with the cracking strain in the finite element analysis (Bažant and Oh 1983). When the cracking strain is assumed to be uniformly distributed over the crack band, the cracking strain of the mortar can be approximately calculated using Eq. (6.13) (Tao and Chen 2015; Yao and Wu 2016). It can be seen that a higher cracking strain is indicative of a higher crack opening width, and the cracking strain can be used to approximately evaluate the extent of cracking.

$$w = \varepsilon^{cr} h \quad (6.13)$$

where h is the crack band width, w is the crack opening width, and ε^{cr} is the cracking strain.

6.3.1.4 Shear Retention Factor

During the post-cracking stage, the cracked mortar can still transfer shear forces through aggregate interlock or shear friction, which is termed as shear retention (Hu et al. 2004; Safdar et al. 2016). The use of reduced shear modulus not only improves the realism of the cracking representation but also removes some numerical difficulties caused by the singularity of the composite material's constitutive matrix (Hu and Schnobrich 1990). Numerous analytical results have shown that the shear retention value (between 0 and 1) does not seem to be critical but is greater than 0 to avoid numerical instability (Hu and Schnobrich 1990; Safdar et al. 2016). The value of 0.5 has been successfully adopted by Barth and Wu (Barth and Wu 2006), which is also used in this analysis.

6.3.1.5 Poisson's Ratio

The Poisson's ratio (ν) of concrete under uniaxial compressive stress ranges from about 0.15–0.22, with a representative value of 0.19 or 0.20 (Hu et al. 2004; Safdar et al. 2016). In this study, the Poisson's ratio of mortar is assumed to be 0.2 (Garzón-Roca et al. 2012).

6.3.2 Kenaf Fibers

The stress-strain curve of kenaf fibers exhibited linear behavior and brittle failure. In **Table 5.1**, the tensile strength and diameter of kenaf fibers are listed. In the simulation, AKF reinforced mortar beams are taken as examples to be modeled. The modulus of elasticity of AKF obtained in this study is 44.69 GPa. The Poisson's ratio of kenaf fibers can be approximately defined as 0.324 (Mariselvam and Logesh). Mahjoub et al.

summarized the density of kenaf fibers from different origins, and the range is between 0.6 and 1.5 (Mahjoub et al. 2014). In this study, the middle value 1.05 is used.

6.3.3 Analytical Model

A 3D simply supported beam was modeled using the nonlinear finite element software, MSC MARC, as shown in **Fig. 6.4**. The eight-node solid element (type 7) was used to model mortar. To improve the shear (or bending) characteristics, the assumed strain is flagged through the Geometric Properties option in MSC MARC (Marc 2010). Also, to eliminate stress concentration and simulate the actual situation, the supporters and the loading location are modeled using some narrow steel elements (type 7). The modulus of elasticity and Poisson's ratio of steel elements are defined as 200 GPa and 0.3. The displacement-controlled loading was applied to the mid-span of the beam in 50 steps.

Fig. 6.4. Simply supported beam model

The contribution of kenaf fibers was taken into account in a homogenized way that kenaf fibers are assumed to be well dispersed in each mortar element. The orientation of fibers was considered along the longitudinal direction of mortar beams, and an efficiency factor 0.5 was used for the simplification to offset the random fiber distribution/orientation in reality (Georgiadi-Stefanidi et al. 2011). Kenaf fibers were modeled using rebars that are placed in the hollow isoparametric four-node membrane rebar element (type 147). Then the membrane rebar elements were embedded into solid mortar elements using the INSERT option. The reinforcement in a mortar element was schematically shown in **Fig. 6.5**. Since the mortar beam is discretized into mortar elements in several layers and a layer of fibers

is arranged in each mortar element, the fibers are automatically arranged in several layers consistent with the mortar elements. It has to be noted that the stick-slip effect (pullout behavior) between fibers and mortar is not considered in this model.

Fig. 6.5. Schematic of reinforcement in mortar

6.4 Results and Discussions

6.4.1 Crack Pattern at Failure

The crack pattern at failure (maximum load reached) of mortar specimens under compression is found to be greatly influenced by the fiber dosage rather than the fiber type. Take specimens with 0.25%, 0.5%, and 0.75% AKF as examples, together with the control, the crack pattern at failure of mortar cubes is compared in **Fig. 6.6**. **Fig. 6.6(a)** shows that the control cubes exhibit a typical brittle failure. The outer surface of the control cubes is stripped completely, and only the core part remains. **Fig. 6.6(b)** shows that although 0.25% AKF cannot prevent the occurrence of stripping, the remaining core part is enlarged. **Fig. 6.6(c)** shows that 0.5% AKF continues to reduce the stripped part, and the remaining part is becoming larger and larger. **Fig. 6.6(d)** shows that when 0.75% AKF is used, the mortar cubes fail differently that no stripping occurs, and the cubes remain intact except for some large developed cracks. Generally, with the increase of fiber dosage from 0 to 0.75%, the mortar cubes tend to be more ductile since the reinforcing fibers can limit crack propagation and hold the mortar cubes together.

Fig. 6.6. Crack pattern of mortar cubes for (a) Control, (b) AKF0.25, (c) AKF0.5, and (d) AKF0.75

The crack pattern of mortar beams is analyzed by examining the cracks on the side faces at the mid-span of beams immediately while cracking. Take specimens with 0.25%, 0.5%, and 0.75% AKF as examples again, together with the control, the crack pattern is shown in **Fig. 6.7**. For the control, **Fig. 6.7(a)** shows that a single large crack exists obviously while the beams are broken. However, for mortar beams with 0.25%, 0.5%, and 0.75% AKF, **Fig. 6.7(b-d)** show that although the similar single crack remains, with the increase of fiber dosage, the length and width of cracks gradually decrease. This is because kenaf fibers can bridge the two broken sections of beams after cracking, and a higher fiber dosage leads the mortar beams to exhibit a more ductile failure pattern.

6.4.2 Compressive Strength and Flexural Strength

The effects of fiber dosage and fiber type on compressive strength and flexural strength of all specimens are shown in **Fig. 6.8(a)** and **Fig. 6.8(b)**, respectively. It is noted that in these figures, the three dashed lines are the upper bound (average+deviation), mean, and lower bound (average-deviation) values of the corresponding control mix. This notation also applies to **Fig. 6.9**.

First of all, regardless of fiber dosage and fiber type, **Fig. 6.8** shows that compared to the control, the addition of kenaf fibers to mortar reduces the compressive strength and flexural strength of mortar. The reduction in strength is mainly due to the increased voids in mortar caused by kenaf fibers, which is evidenced by the reduced density (see Table 6.2). One way is that kenaf fibers can absorb some mixing water due to hydrophilic nature (Jo et al. 2016) and lower the flowability of mortar, which can lead to increased voids in mortar. Another way is that kenaf fibers themselves can introduce some voids because of the hollow structure (Ismail et al. 2019). Even the nanoindentation test performed in the interfacial transition zone around kenaf fibers revealed a significant volume fraction of porosity, a high percentage of low-density calcium silicate hydrate (C-S-H), and a low

percentage of high-density C-S-H (Zadeh and Bobko 2014), which is indicative of a poor fibers/matrix adhesion responsible for the reduced strength (Benmansour et al. 2014). This is also confirmed by the microstructure analysis shown in section 6.4.5 of this study. Besides, kenaf fibers can easily clump in mortars and also can negatively affect cement hydration (Amel et al. 2014), both of which are not beneficial to the strength development of mortar. Through **Fig. 6.8**, it can also be seen that the compressive strength is more negatively affected than flexural strength by kenaf fibers.

With the increase of fiber dosage, **Fig. 6.8** shows that both the compressive strength and flexural strength exhibit a descending trend. This is due to not only the reduced density (see Table 6.2) but also the increased possibility of agglomeration, which can deteriorate the strength.

Of all three types of fibers (RKF, AKF, and AHPKF), although no obvious difference can be seen in density (see Table 6.2), **Fig. 6.8** indicates that in general, RKF seems to lead to the worst compressive strength and flexural strength. This is not only because AKF and AHPKF have less hemicellulose, lignin, and extractives than RKF (see **Table 5.1**) that can reduce the negative effect on cement hydration but also because AKF and AHPKF have a slightly rougher surface than RKF (see Fig. 5.3). Comparing AKF and AHPKF reinforced mortars, there is no significant difference in strength; however, mostly, AKF seems to perform a little better than AHPKF.

(b)

Fig. 6.8. Effect of fiber dosage and fiber type on (a) compressive strength and (b) flexural strength (error bar is from standard deviation, which is applicable to all related figures in this study)

6.4.3 Modulus of Elasticity and Flexural Toughness

The effects of fiber dosage and fiber type on modulus of elasticity and flexural toughness of all specimens are shown in **Fig. 6.9(a)** and **Fig. 6.9(b)**, respectively. **Fig. 6.9(a)** shows that compared to the control, for mortars with kenaf fibers, the modulus of elasticity

is not changed significantly and is still within the range of the control specimens. Moreover, the change of modulus of elasticity with the fiber dosage and fiber type is not obvious, and no clear trend can be seen.

However, **Fig. 6.9(b)** shows that mortars with kenaf fibers have higher flexural toughness than the control. The increase of flexural toughness is mainly due to the fact that after cracking, the stress is transferred from the matrix to the fibers, and the slippage of fibers relative to the matrix is the main reason for energy dissipation and higher toughness (Andiç-Çakir et al. 2014; Khan and Ali 2018). Similar conclusions that the presence of kenaf fibers in concrete decreases the compressive strength and flexural strength but increases the flexural toughness were also reported by other researchers (Elsaid et al. 2011; Lam and Yatim 2015). Through **Fig. 6.9(b)**, it can also be seen that the flexural toughness can be increased obviously with the increasing fiber dosage, and the improvement percent can be 10.66-28.86%, 64.54-81.80 %, and 70.25-92.80 % for the fiber dosage of 0.25%, 0.5%, and 0.75%, respectively. Besides, of all three types of fibers (RKF, AKF, and AHPKF), AKF seems to lead to the highest flexural toughness.

(a)

(b)

6.4.4 Effect of the Addition of Superplasticizer

In this study, the superplasticizer is added into 0.75% kenaf fibers reinforced mortars to achieve a good flowability, and the effect of superplasticizer on compressive strength, flexural strength, modulus of elasticity, and flexural toughness is shown in **Fig. 6.10**. It can be seen that the compressive strength, flexural strength, modulus of elasticity, and flexural toughness of mortars all have been improved, which is mainly attributed to the increased density (see Table 6.2). Also, **Fig. 6.10(a-b)** shows that the addition of superplasticizer can lead the flexural strength to the same level as the control while the compressive strength is still slightly lower than that of the control.

6.4.5 Microstructure

The microstructure of the fracture surfaces of RKF0.5, AKF0.5, and AHPKF0.5 is shown in **Fig. 6.11**. On all of the left-panel figures, irrespective of fiber type, it can be clearly seen that some kenaf fibers are pulled out of the mortar matrix under the flexural test, which indicates the weak bonding between kenaf fibers and the mortar matrix. By carefully examining the right-panel figures, some slight differences can be observed. **Fig. 6.11(a)** shows that a thin layer of cementitious materials exists on the surface of RKF, and also a void exists surrounding RKF, which is not beneficial to the mechanical properties. **Fig. 6.11(b)** shows that some uneven imprints are left on the mortar matrix by AKF due to rough surface, which indicates that a bonding exists to a certain extent between AKF and the mortar matrix even if it is not strong enough. **Fig. 6.11(c)** shows that the fibrillation of AHPKF occurs and some individual fibrils can be clearly seen in one bundle of AHPKF, which is because some substances, mainly hemicellulose and lignin, have been removed

(Williams et al. 2011). This can further increase the contact area of AHPKF with the mortar matrix and can be helpful to the mechanical properties. Generally, through microstructure analysis, it can be seen that the bonding between these three types of fibers (RKF, AKF, and AHPKF) and the cementitious matrix is not good enough due to the obvious fiber slippage, which is partly responsible for the worse mechanical properties of fiber reinforced mortars compared to the control. Meanwhile, it can also be seen that AKF and AHPKF can behave better than RKF in bonding due to the modified surface texture, which can lead to mortars with AKF or AHPKF have better mechanical properties than those with RKF.

6.4.6 Finite Element Analysis

6.4.6.1 Parameter Optimization for Mortar without Kenaf Fibers (The Control)

For mortar without kenaf fibers (the control), the compressive strength (55.16 MPa) is directly obtained from the experiment. The modulus of elasticity and tensile strength can be initialized as 34.91 GPa and 3.33 MPa using Eq. (6.7) and Eq. (6.8), respectively. Together with other parameters introduced in section 6.3.1 of this paper, the load-deflection curve from finite element analysis can be obtained, which is denoted as “Control-FEA (original)” in **Fig. 6.12**. By comparing with the load-deflection curves directly from the experiment (also included in **Fig. 6.12**), it is clearly seen that there is a significant discrepancy between finite element analysis and experiment. Therefore, an optimization process is needed by adjusting the tensile strength and modulus of elasticity to make the curve from finite element analysis closely approach the experimental result as much as possible. Eventually, the modified tensile strength and modulus of elasticity are 4.95 MPa and 25 GPa, respectively, which are adopted as the fundamental parameters of mortar for

the following analysis. The resulting modified load-deflection curve from finite element analysis is also plotted in **Fig. 6.12**, which is denoted as “Control-FEA (modified)”. The corresponding peak load, deflection at peak, and flexural strain at peak from experiment and finite element analysis are compared in **Table 6.3**, which are in good agreement.

Fig. 6.12. Comparison of load-deflection curves of the control from FEA and experiment

Table 6.3 Comparison of experiment with finite element analysis for the control

Specimens	Peak load (N)	Deflection at peak (δ , mm)	Flexural strain at peak (ε)*
Control-Experiment	257.20±26.24	0.109±0.011	0.000255±0.000026
Control-FEA	256.11	0.102	0.000219

Note: * The experimental value of ε is calculated based on δ using $\varepsilon=6*\delta*h/l^2$, in which h and l are height and length of a beam.

6.4.6.2 Stress and Cracking Strain of Mortar with Kenaf Fibers

Before examining the stress and cracking strain within fiber reinforced mortars, it is necessary to compare the experimental and FEA results to assure the simulation is in agreement with the experiment. Take mortar with 0.75% AKF for example, by using the parameters of mortar matrix obtained from previous section ($f_c'=55.16\text{MPa}$, $E_c=25\text{GPa}$, $f_t'=4.95\text{MPa}$), the load-deflection curve (in red color) from the finite element analysis is compared to those (in black color) of four replicate specimens of AKF0.75P0.2 from the

experiment, as shown in **Fig. 6.13**. It can be seen that the load-deflection curve from finite element analysis is consistent with the experimental result. The peak loads from the experiment and finite element analysis are 274.54 ± 27.19 N and 256.72 N, respectively. Here, it has to be noted that since the pullout behavior of kenaf fibers is not modeled, the stress of kenaf fibers will continue increasing linearly with the strain after mortar cracks, and the load-deflection curve after the peak load will not be as accurate as the reality. This is one limitation of this model. However, since during the modelling of interest, the tensile stress of kenaf fibers is within their tensile capacity, and the load (50.39 ± 19.37 N) that the specimen can bear immediately once cracking from the experiment is much close to 53.91 N obtained from finite element analysis, it is appropriate to approximately simulate the 0.75% AKF specimen.

Fig. 6.13. Comparison of load-deflection curves of mortars with 0.75% AKF from finite element analysis and experiment

To visually identify the development of stress and cracking strain with deflection beyond cracking, three deflections are selected to assist in examining the stress and cracking strain contour bands. From the simulated curve in Fig. 6.13, it can be seen that

the deflection of 0.102 mm that corresponds to the peak load where the cracking occurs is very critical, which is taken as the “1” deflection. Beyond the “1” deflection, there is an abrupt load decrease in the simulated curve, and the deflection of 0.108 mm closest to the “1” deflection is taken as the “2” deflection. The third deflection can be any deflection that is far from the “2” deflection to reveal the situation of specimens subject to a certain deflection from cracking, which is taken as 0.3mm (denoted as “3” in Fig. 6.13). The stress and cracking strain contour bands of the control and AKF0.75 corresponding to these three deflections are shown in **Fig. 6.14** and **Fig. 6.15**, respectively. Positive and negative values in the legend are indicative of tensile stress and compressive stress, respectively. **Fig. 6.14** shows that before cracking (“1”), the stress contour band of AKF0.75 is almost the same as that of the control. However, after cracking (“2” and “3”), the compressive stress at the top of AKF0.75 is significantly higher than that at the top of the control. Moreover, when the deflection is 0.108mm (“2”), a slight difference can be seen for the control and AKF0.75. Compared to the control, a clear tensional zone (shown in red color in the related figure) near the compressive zone exists for AKF0.75. This is because after cracking, the control completely fails, and no tensional zone exists; however, for AKF0.75, the failure is progressive, and the tensional zone shifts upward. **Fig. 6.15** shows that the cracking strain of AKF0.75 is less than that of the control specimen in general. Moreover, once cracks appear (see “2” section in **Fig. 6.15**), the cracking strain of the control specimen can rapidly develop from the bottom to the top; however, the cracking strain of AKF0.75 does not develop to the whole depth of beams immediately, which indicates that the crack propagation is slowed down by fibers. This is mainly because, after the specimen cracks, kenaf fibers can bridge the cracked sections and delay crack propagation.

Fig. 6.14. Stress contour band of (a) the control and (b) AKF0.75

Fig. 6.15. Cracking strain contour band of (a) the control and (b) AKF0.75

6.4.6.3 Effect of Fiber Dosage on Load-Bearing Capacity and Cracking Strain

The load-deflection curves and cracking strain-deflection curves of mortar beams with 0.25%, 0.5%, and 0.75% AKF are shown in **Fig. 6.16(a)** and **Fig. 6.16(b)**, respectively.

Fig. 6.16(a) shows that the peak load is not increased significantly with the fiber dosage increasing from 0.25% to 0.75%; however, the residual load that is defined as the load that

a specimen can bear after the peak load is reached is increased. A higher residual load can prevent a specimen from immediate full collapse after the peak load has been reached and enable the specimen to have a certain load bearing capacity at the post-cracking stage. The cracking strain appears (shown in **Fig. 6.16(b)**) after the cracking occurs, and it increases with the increase of deflection of the specimen. **Fig. 6.16(b)** shows that the cracking strain is reduced significantly with the increasing fiber dosage, especially when the fiber dosage increases from 0 to 0.5%, which is consistent with the reduced length and width of cracks observed in the experiment (see Fig. 6.7). The reduced cracking strain represents the reduced extent of cracking, indicating a slow crack propagation after the mortar cracks. Therefore, with the increase of fiber dosage, the mortar is less prone to exhibit a sudden brittle failure. Generally, through the finite element analysis, it can be seen that a low content fiber cannot improve the peak load but can improve the residual load and reduce the cracking strain significantly.

Fig. 6.16. (a) Load-deflection curves and (b) cracking strain-deflection curves of mortar beams with varying AKF dosages

6.5 Conclusions

In this study, raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) with different dosages (0.25%, 0.5%, and 0.75% by weight of cement) were incorporated in the mortar to evaluate their impact on the flexural behavior of mortar. Compressive test, flexural test, and SEM test were conducted. Moreover, the finite element analysis was adopted to assist in examining the stress and cracking strain of specimens. Several important conclusions can be drawn.

The presence of kenaf fibers in mortars can reduce compressive strength and flexural strength, which can be attributed to several factors, such as the reduced density of specimens, weak interfacial adhesion, and negatively affected cement hydration, etc. However, the flexural toughness can be increased significantly due to fiber bridging over cracks. Moreover, the addition of superplasticizer can improve the strength and toughness obviously through increasing the density of specimens.

With the increase of fiber dosage, the specimens tend to fail in a more ductile manner that the mortar cubes tend to be more intact while failing and the mortar beams tend to have smaller cracks at the mid-span after cracking. Moreover, the compressive strength and flexural strength are reduced, which is mainly due to the reduced density of specimens. The change of modulus of elasticity is not obvious. However, the flexural toughness is enhanced significantly, and the improvement can be 10.66-28.86%, 64.54-81.80 %, and 70.25-92.80 % for the fiber dosage of 0.25%, 0.5%, and 0.75%, respectively.

By comparing specimens with RKF, AKF, and AHPKF, although no significant difference in density and modulus of elasticity can be seen, RKF seems to lead to the worst compressive strength, flexural strength, and flexural toughness. This is mainly because

RKF has the largest amount of hemicellulose, lignin, and extractives and the relatively smooth surface. Moreover, by the comparison of AKF and AHPKF, the difference in mechanical properties is slight, but mostly AKF seems to be a little better than AHPKF.

The microstructure analysis shows that regardless of fiber type, the fiber pullout occurs due to a weak bonding, which is not beneficial to the mechanical properties of mortar. Meanwhile, AKF and AHPKF seem to behave better than RKF in the bonding in their ways, which lead mortars with AKF or AHPKF to have better mechanical properties than those with RKF.

The stress and cracking strain distribution of AKF0.75 and the control were examined in detail through finite element analysis. Before cracking 0.75% AKF does not change the stress distribution within specimens obviously, but after cracking it can increase the stress level in the compressive zone, indicating a higher residual load. Also, 0.75% AKF can slow down crack propagation and reduce cracking strain significantly. Lastly, finite element analysis indicates that a low fiber dosage (up to 0.75%) cannot improve the peak load significantly but can increase the residual load and reduce the cracking strain. More fibers are needed to be incorporated into mortar beams if the peak load needs to be improved obviously.

Given that with the increase of fiber dosage from 0.25% to 0.75%, the strength is reduced yet the toughness is increased, and also the cracking strain is significantly reduced until 0.5% fiber dosage, 0.5% may be the best fiber dosage. If the volume fraction of aggregates in concrete is assumed as 60%-80% and the specific gravity of kenaf fibers is approximately assumed as 1, 0.5% fiber dosage by weight of cement will be converted into

0.12-0.24% fiber dosage by volume of concrete, which is the recommended value in improving the flexural properties of mortar.

CHAPTER 7 CONCLUSIONS AND FUTURE WORK

7.1 Conclusions

In this dissertation, the hydration, shrinkage, cracking, and mechanical properties of cementitious materials with lignocellulosic biomass wastes were studied. Three types of lignocellulosic biomass wastes (hemp powders, wood chips, and kenaf fibers) at different scales were recycled and reutilized to partially replace cement, partially replace sand, or serve as reinforcements, respectively, in cementitious materials. In order to improve their effects on the performance of cementitious materials, these lignocellulosic biomass wastes were modified as required using physical or chemical treatment methods. The effect of untreated and treated lignocellulosic biomass wastes on cementitious materials was examined in detail. Some important conclusions can be drawn as follows.

7.1.1 Effect of Hemp Powders on Cement Hydration

Hemp powders were used to partially replace cement by 5% and 10% (by weight), respectively, which were found to delay cement hydration and affect the formation of hydration products. Even, for some cases, after 7-day hydration, they were still at the dormant phase, and the hydration was very slow.

Alkaline treatment (saturated $\text{Ca}(\text{OH})_2$ solution) on hemp powders could remove some hemicellulose and increase the relative cellulose content, which could mitigate their delaying effect on cement hydration. Moreover, the washing process following the alkaline

treatment could further reduce the delaying effect by removing more hemicellulose and other unbeneficial substances.

Compared to coarse hemp powders, fine hemp powders had a higher specific surface area to contact with cement paste, which could lead them to result in a more delaying effect on cement hydration.

Compared to 5% replacement, 10% replacement could delay cement hydration more significantly, and the hydration could be almost completely inhibited during 7-day testing. The result indicated that the 10% replacement could be the limit replacement.

7.1.2 Effect of Wood Chips on Mechanical Properties of Mortar

Wood chips were used to partially replace silica sand by 5% and 10% (by weight), respectively, in mortars, which was found to reduce the compressive strength, flexural strength, and modulus of elasticity, but increase the toughness.

Compared to untorrefied wood chips, torrefied wood chips had a slightly rougher surface, which could increase the bonding with the cementitious matrix. Therefore, mortars with torrefied wood chips had higher strength and modulus of elasticity than those with untorrefied wood chips; however, the toughness was lower.

7.1.3 Effect of Chemical Treatment on Kenaf Fibers

Some inorganic chemicals (sodium hydroxide, potassium permanganate, potassium dichromate, hydrogen peroxide, and sodium chlorite) were used to modify kenaf fibers, which were found to remove some hemicellulose, lignin, and extractives of kenaf fibers. After chemical treatment, the moisture sorption was reduced, and the crystallinity index, surface roughness, and tensile strength were improved.

Compared to raw kenaf fibers, solely alkaline treatment could lead to relatively good improvement. Moreover, of all chemical treatments, alkaline-hydrogen peroxide treatment exhibited the best generally.

7.1.4 Effect of Kenaf Fibers on Shrinkage and Cracking of Cement Paste

Raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) with the dosages of 0.25% and 0.5% by weight of cement were used as reinforcements in cement paste, which were found to reduce the autogenous shrinkage and drying shrinkage cracking significantly.

Compared to 0.25% fiber dosage, 0.5% fiber dosage could reduce the autogenous shrinkage and drying shrinkage cracking more. Of all three types of kenaf fibers, alkaline-hydrogen peroxide treated fibers were the best.

7.1.5 Effect of Kenaf Fibers on Flexural Behavior of Mortar

Raw kenaf fibers (RKF), alkaline treated kenaf fibers (AKF), and alkaline-hydrogen peroxide treated kenaf fibers (AHPKF) with the dosages of 0.25%, 0.5%, and 0.75% by weight of cement were used as reinforcements in mortars, which were found to reduce compressive strength and flexural strength due to the increased voids but increase flexural toughness significantly. Moreover, with the increase of fiber dosage from 0.25% to 0.75%, the compressive strength and flexural strength were reduced; however, the flexural toughness was improved significantly. The addition of superplasticizer could improve the compressive strength, flexural strength, and flexural toughness compared to those without superplasticizer.

Of all three types of fibers (RKF, AKF, and AHPKF), RKF led to the worst compressive strength, flexural strength, and flexural toughness. Moreover, by the

comparison of AKF and AHPKF, the difference in mechanical properties was slight, but mostly AKF seemed to be a little better than AHPKF.

The microstructure analysis showed that the fiber pullout occurs due to weak bonding between the fibers and the mortar matrix. AKF and AHPKF seemed to behave better than RKF in the bonding.

The finite element analysis indicated that a low fiber dosage (up to 0.75%) could not improve the peak load significantly but could increase the residual load, slow down crack propagation, and reduce the cracking strain significantly.

7.1.6 Recommendations

Based on this study, the concrete developed with lignocellulosic biomass wastes can be used for non-structural elements, such as pavement and roof, where the requirement for strength is relatively low. Moreover, since lignocellulosic biomass wastes have the ability of improving the toughness of concrete significantly, they can be suitable for the foundation floor for machinery in factories or other places where there is a high requirement for energy absorption when concrete is exposed to dynamic load.

The allowable dosages of hemp powders, wood chips, and kenaf fibers in concrete are different. When the volume fraction of aggregates in concrete is assumed as 60-80% and the specific gravity of hemp powder is approximately assumed as 1, it is recommended that the limit dosage of hemp powders is 2.24-4.48% by volume of concrete (10% dosage limit by weight of cement), the dosages of wood chips by volume of concrete are roughly 5-10% for OW and HTW (10% by weight of sand) and 2.5-5% for LTW (5% by weight of sand), respectively, and the dosage of kenaf fibers by volume of concrete is 0.12-0.24% (0.5% by weight of cement).

Even if this research does not cover the long-term behavior of concrete with lignocellulosic biomass, based on the existing literature that lignocellulosic biomass can be degraded in the alkaline environment of concrete, the bonding between lignocellulosic biomass and the matrix may be compromised in the long run. This can hurt the mechanical properties of concrete. However, based on this research, some physical treatment (such as torrefaction treatment) and chemical treatment (such as alkaline treatment) can remove some easily degraded substances (such as hemicellulose and impurities) from lignocellulosic biomass, which is believed to improve the long-term behavior of concrete compared to those with raw lignocellulosic biomass. Therefore, it is recommended to modify lignocellulosic biomass physically or chemically prior to being used in concrete.

7.2 Future Work

This work suggests that the lignocellulosic biomass can affect the hydration, shrinkage, cracking, and mechanical properties of cementitious materials. Some future work on this topic can be further studied.

- Lignocellulosic biomass is found to delay cement hydration, which is mainly attributed to some saccharides generated from the degradation of lignocellulosic biomass. Since different saccharides may have differing effects on cement hydration and also the degradation of lignocellulosic biomass can produce some other substances aside from saccharides, the delaying mechanism of cement hydration can be further studied in detail.
- In this work, some physical and chemical treatments are applied to lignocellulosic biomass, which can increase cost and energy consumption. The treatment method can be optimized to improve its economy.

- Lignocellulosic biomass can be degraded in the alkaline environment of cementitious materials, and their effects can vary with time in the long run. Therefore, the durability of cementitious materials with lignocellulosic biomass can be studied.
- To reduce the degradation of lignocellulosic biomass in cementitious materials, an alternative way is to lower the alkalinity of cementitious materials. The application of lignocellulosic biomass to low alkaline cement can be studied.
- Lignocellulosic biomass in cementitious materials can absorb much water, which can reduce the flowability and increase the porosity of cementitious materials. When a large amount of lignocellulosic biomass is used, superplasticizer should be added to improve the flowability. With the addition of superplasticizer, the effect of lignocellulosic biomass on cementitious materials can be studied.
- Lignocellulosic biomass is much lighter than the cementitious materials, and they can be possibly used to develop lightweight concrete in the future study.
- Due to the high water absorption capacity, the application of lignocellulosic biomass as an internal curing agent for concrete can be studied.
- In the finite element analysis in this research, there is one limitation with the model that the fiber orientation and fiber pullout behavior are not considered realistically. To realistically model the flexural behavior of cementitious materials with kenaf fibers using finite element method, the fiber orientation and fiber pullout behavior can be considered in the future work.

APPENDIX

Correction for chemically bound water calculation

TGA test was conducted on pure cement powder, each type of hemp powders, and paste mixtures according to the procedure introduced above. The weights of pure cement powder at 105 °C and 1100 °C are denoted as C_1 and C_2 , respectively. The weights of hemp powders at 105 °C and 1100 °C are denoted as H_1 and H_2 , respectively. The weights of cement paste mixtures at 105 °C and 1100 °C are denoted as W_1 and W_2 , respectively. The loss on ignition of pure cement powder between 105 °C and 1100 °C is $(C_1 - C_2)/C_1$, denoted as L_c . The weight loss percentage of hemp powders between 105 °C and 1100 °C is $(H_1 - H_2)/H_1$, denoted as L_h . The weight loss of the tested cement paste between 105 °C and 1100 °C is calculated as shown in eq. (1).

$$W_t = W_1 - W_2 \quad (1)$$

where W_1 is the weight of cement paste at 105 °C; W_2 is the weight of cement paste at 1100 °C.

The weight loss of cement paste between 105 °C and 1100 °C (W_t) includes several main parts: (1) decomposition of chemically bound water; (2) loss on ignition of cement powder used; (3) decomposition of hemp powders if involved; and (4) calcium carbonate

decomposition. Therefore, to calculate chemically bound water, W_i needs to be modified. It should be noted that the calcium carbonate decomposition correction is not considered because it is hard to be exactly quantified in this study. Therefore, the calculated degree of hydration should be a little bit higher than its real value, but it does not affect the comparative analysis of all samples. Other steps for weight correction of W_i are shown as follows:

(1) Hemp powder decomposition correction (W_h)

For cement paste with hemp powders, W_i needs to be modified by considering the decomposition of hemp powders. Assuming the total weight of hemp powders used in cement paste is H_t . Based on the weight loss percentage of hemp powders between 105 °C and 1100 °C, L_h , the remaining weight of hemp powders incorporated into cement paste will be $(1 - L_h) \times H_t$ when cement paste is heated to 1100 °C. Because the weight of cement paste at 1100 °C is W_2 , the weight of ignited cement will be $W_2 - (1 - L_h) \times H_t$ by excluding the remaining hemp powders. Based on the loss on ignition of pure cement powder, L_c , the total weight of cement powder used will be deduced as $[W_2 - (1 - L_h) \times H_t]/(1 - L_c)$. If the replacement percentage of cement powder with hemp powders is denoted as r , then the total weight of hemp powders used will be $[W_2 - (1 - L_h) \times H_t]/[(1 - L_c) \times (1 - r)]$. Finally, an equilibrium can be achieved as shown in eq. (2), by which H_t can be solved (shown in eq. (3)). The total weight of cement powder used can be calculated by substituting H_t into $[W_2 - (1 - L_h) \times H_t]/(1 - L_c)$, as shown in eq. (4), which is denoted as C_i . If no hemp powders are used in cement paste, the replacement content r is 0, then C_i will be simplified into $W_2/(1 - L_c)$.

$$\frac{[W_2 - (1 - L_h) \times H_t] \times r}{(1 - L_c) \times (1 - r)} = H_t \quad (2)$$

$$H_t = \frac{W_2 \times r}{(1-L_h) \times r + (1-L_c) \times (1-r)} \quad (3)$$

$$C_t = \frac{W_2 \times (1-r)}{(1-L_h) \times r + (1-L_c) \times (1-r)} \quad (4)$$

where H_t is the total weight of hemp powders used in cement paste; C_t is the total weight of cement powder used in cement paste; W_2 is the weight of cement paste at 1100 °C; r is the replacement percentage of cement powder with hemp powders; L_h is the weight loss percentage of hemp powders between 105 °C and 1100 °C; L_c is the loss on ignition of pure cement powder (between 105 °C and 1100 °C).

Based on the total weight of hemp powders used in cement paste, H_t , and the weight loss percentage of hemp powders between 105 °C and 1100 °C, L_h , the weight loss of hemp powders used in cement paste between 105 °C and 1100 °C can be obtained as shown in eq. (5), denoted as W_h . W_h is hemp powder decomposition correction content, which will be subtracted from W_t for calculating chemically bound water if hemp powders involved.

$$W_h = H_t \times L_h \quad (5)$$

where W_h is the weight loss of hemp powders used in cement paste between 105 °C and 1100 °C; H_t is the total weight of hemp powders used in cement paste; L_h is the weight loss percentage of hemp powders between 105 °C and 1100 °C.

(2) Loss on ignition correction (W_l)

Based on the loss on ignition of pure cement powder, L_c , the weight loss of cement powder used between 105 °C and 1100 °C will be $C_t \times L_c$ as shown in eq. (6), denoted as W_l . W_l is the loss on ignition correction content, which will be subtracted from W_t for calculating chemically bound water.

$$W_l = C_t \times L_c \quad (6)$$

where W_l is the weight loss of cement powder used between 105 °C and 1100 °C; C_t is the total weight of cement powder used in cement paste; L_c is the loss on ignition of pure cement powder.

With the abovementioned correction, the chemically bound water (w_b) of cement paste with hemp powders can be calculated by using eq. (7). Fig. 10 also schematically plots the correction procedure of weight loss of cement paste.

$$W_b = W_t - W_l - W_h \quad (7)$$

where W_t is the total weight loss of cement paste between 105 °C and 1100 °C; W_l is loss on ignition correction, namely the weight loss of cement powder used between 105 °C and 1100 °C; W_h is hemp powder decomposition correction, namely the weight loss of hemp powders used between 105 °C and 1100 °C.

Fig. 10. Schematic of weight-loss correction of cement paste

Degree of hydration calculation

For cement paste with hemp powders, the weight of ignited cement is corrected to be $W_2 - (1 - L_h) \times H_t$ that has been introduced in “Hemp powder decomposition correction” section. The chemically bound water per unit gram of ignited cement then can

be calculated by using $W_b/[W_2 - (1 - L_h) \times H_t]$, denoted as W_{bg} . By substituting H_t obtained in eq. (3) into $W_b/[W_2 - (1 - L_h) \times H_t]$, W_{bg} can be obtained as shown in eq. (8). If no hemp powders are used in the paste mixtures, the replacement content r is 0, and then W_{bg} will be simplified into W_b/W_2 .

$$W_{bg} = \frac{W_b \times [(1 - L_h) \times r + (1 - L_c) \times (1 - r)]}{W_2 \times (1 - r) \times (1 - L_c)} \quad (8)$$

where W_{bg} is the chemically bound water per unit gram of ignited cement; W_b is the chemically bound water of cement paste; W_2 is the weight of cement paste at 1100 °C; r is the replacement percentage of cement powder with hemp powders; L_h is the weight loss percentage of hemp powders between 105 °C and 1100 °C; L_c is the loss on ignition of pure cement powder (between 105 °C and 1100 °C).

For completely hydrated Type I Portland cement, the chemically bound water per unit gram of ignited cement ranges from 0.23-0.25 (Pane and Hansen 2005). In this study, 0.25 is adopted. Therefore, the degree of hydration (DoH) can be calculated by using W_{bg} divided by 0.25, as shown in eq. (9). If no hemp powders are used in paste mixtures, the replacement content r is 0, and then DoH will be simplified into $W_b/(0.25 \times W_2)$.

$$DoH = \frac{W_b \times [(1 - L_h) \times r + (1 - L_c) \times (1 - r)]}{0.25 \times W_2 \times (1 - r) \times (1 - L_c)} \quad (9)$$

where DoH is degree of hydration of cement paste; W_b is the chemically bound water of cement paste; W_2 is the weight of cement paste at 1100 °C; r is the replacement percentage of cement powder with hemp powders; L_h is the weight loss percentage of hemp powders between 105 °C and 1100 °C; L_c is the loss on ignition of pure cement powder (between 105 °C and 1100 °C).
